Delirium represents a tremendous problem in the ICU. The unpredictable behavior of patients experiencing delirium can be challenging to manage and a risk to both the patient and the hospital staff. Delirium itself can be linked to morbidity while in the ICU. Furthermore, delirium is associated with a significant decline long after the patient is discharged from the hospital.

The incidence of delirium varies based on the specific patient population but has been reported to be as high as 80%.¹ One group found that neurology/neurosurgical patients were at the highest risk, followed by trauma patients, and then medical intensive care patients. Surgical ICU patients were at the lowest risk²; however, this result has not been well validated across multiple institutions.

Delirium is usually associated with agitation (i.e., agitated delirium), but this is not a necessity. Agitated delirium describes a syndrome of excessive motor activity, usually nonpurposeful and associated with internal tension. Delirium can also be a quiet confusion that can be difficult to discern by the examining physician. In contrast, the term *mixed delirium* usually denotes alternating periods of quiet confusion and aggressive, nonpurposeful behavior.

For intensivists, agitation is not so much a diagnosis but a consequence of more fundamental etiologies that, when expressed, result in disquietude. As a result of our high-tech hemodynamic monitoring and support devices, we have conferred new types of stresses upon already hemodynamically unstable patients that we never had to deal with in the past. Modern ICUs now have the potential to return critically ill patients to productivity using technological advances in monitoring and closely titrated care, effectively pinning the patient firmly to the bed with tubes and appliances.

In one large study, mixed delirium was found to be the most common subset (54.9%), with hypoactive somewhat less common (43.5%), and hyperactive agitated delirium was rare (1.6%).³ In this same study, hypoactive delirium was reported more frequently in patients at least 65 years of age (41% vs. 21.6%, $P < 0.001$). Agitation episodes that threaten hemodynamic stability are uncommon but are occurring more frequently as ICUs accept wider ranges of critically ill patients for longer periods of time on complex life support systems.

WHY DOES DELIRIUM OCCUR IN CRITICAL CARE UNITS?

By their nature, critical care units are places that require patience and compliance from patients. Sensitive monitoring systems and indwelling catheters frequently occupy every bodily orifice and require relative patient immobility for long periods. Many patients, especially those over 65 years of age, have a mild underlying dementia that is well controlled in their home environment as pattern recognition suppresses the potential underlying cognitive insufficiency.

Thus, when the same patient is admitted to an ICU for any reason, all the previous pattern recognition is lost, and the patient no longer gets by on habit and routine, and the underlying cognitive insufficiency is freely expressed.

The term *ICU psychosis* was introduced to underline the etiologic significance of psychosocial and psychological factors in understanding the syndrome. ICU activities around the clock may lead to a patient's loss of orientation to time. Monotonous sensory input in the

form of unfamiliar, repetitive, and noisy monitoring equipment; prolonged immobilization; brief but frequently interrupted sleep patterns; social isolation; and unfamiliarity with the ICU personnel (which change frequently) eventually contribute to the pre-delirious state.

The term *ICU psychosis* is not an accurate description of the disorder and leads to misleading conclusions. The term *psychosis*, as used in the psychiatric literature, is characterized by persistent disorders of brain functioning in which no specific organic factors may be causally related. In true delirium, organic causation is not only present but also most often stems from outside of the nervous system. Symptoms of ICU-related delirium are extremely random and purposeless, without systematization, while psychotic symptoms are frequently bizarre but well organized and consistent. The term *ICU stress delirium* would be more applicable for organic brain syndromes occurring in the ICU environment.

Although some causes of delirium are well established, others remain controversial based on the study population and methods of evaluating the data. One systematic review found a strong positive association between delirium and the following risk factors: age, dementia, hypertension, coma, Acute Physiology and Chronic Health Evaluation II (APACHE) score, emergency surgery, mechanical ventilation, polytrauma, and metabolic acidosis.⁴ In contrast, the guidelines published by the Society of Critical Care Medicine only found dementia, hypertension, coma, alcoholism, and the APACHE II score to increase the risk of delirium.⁵ A large prospective study of delirium found that only physical restraints increased the risk of delirium.⁶

There has also been some interest in developing a predictive model for delirium. One large study conducted in the Netherlands with different types of ICU patients resulted in the PREdiction of DELIRium in ICu patients (PRE-DELIRIC) model. PRE-DELIRIC had an area under the receiver operating characteristics curve of 0.87, suggesting good validation with CAM-ICU screening, a type of clinical test used to assess delirium. It included the following factors for analysis: age, APACHE II score, coma, type of ICU, infection, metabolic acidosis, morphine use, sedative use, urea concentration, and urgent admission. This model is a promising method for identifying patients who are at a high risk of delirium and could translate into preemptive therapies to prevent delirium occurrence.

As more research is done in this field, the risk factors will likely be better elucidated.

PATHOPHYSIOLOGY OF DELIRIUM

Numerous theories have been proposed to explain the underlying mechanisms of brain failure that result in delirium.

It is thought by many that a major etiology of integrative brain failure is a hemodynamic or metabolic decompensation elsewhere in the body. The ICU environment provides a repository of typical predisposing factors of a hemodynamic or metabolic nature, including acute or chronic organic brain vascular insufficiency, endocrine insufficiency, acute or chronic cardiopulmonary decompensations, multi-organ system insufficiency, relative hypoxia, poor tissue perfusion, multiple medications, and finally, a sleep/wake cycle disruption caused by immobilization, anxiety, and pain. Clinical signs of agitation are likely to be produced when there is an integrative brain failure plus an intense source of sensory stimuli.

Agitation is a visual clue that disintegration of normal motor axis integration is occurring, with a mischanneling of incoming sensory stimuli. Short circuits into phylogenetically old brain areas (e.g., basal ganglia, reticular formation, vestibular nuclei, and often the red nucleus [extrapyramidal system]) produce the clinical picture of uncoordinated and nonpurposeful movements.

Delirium is characterized by global disorders of cognition and wakefulness, as well as an impairment in psychomotor behavior. Major cognitive functions, such as perception, deductive reasoning, memory, attention, and orientation are all globally disordered. There is a growing consensus that delirium is a manifestation of cerebral insufficiency, both generalized and focal, accompanied by a dysregulation of neurotransmitter systems.

The cholinergic system has been strongly implicated in the development of delirium.⁷ Acetylcholine is an important neurotransmitter for consciousness and the level of arousal. Potential mechanisms for delirium include the reduced production of acetylcholine or decreased acetylcholine transmission. Production of acetylcholine is very sensitive to hypoglycemia, oxidative stresses, and substrate deficiencies. Elevated levels of serum anticholinergic activity are also associated with delirium.⁸ Cholinergic function decreases with age, which may explain why age is a predictive factor for delirium. In addition, anticholinergic medications are associated with an increased incidence of delirium.⁹

Higher than normal dopamine levels have also been correlated with the development of delirium. This may be due to either a reduced reuptake of dopamine or an increased release of this neurotransmitter. Hypoxia can also cause the excessive release of dopamine, and psychosis is known to correlate with elevated dopamine levels. The use of haloperidol for the treatment and prevention of delirium has been suggested in part due to its antagonism of the dopamine receptors.¹⁰ Medications that affect the D2 receptor increase the release of acetylcholine in the prefrontal cortex.¹¹ This interesting finding suggests an interaction between dopamine and acetylcholine levels in the development of delirium.

Inflammation may also be an important pathway. Several studies have found positive associations between inflammatory cytokines and the incidence of delirium.^{12,13} In times of physiologic stress, such as a postoperative state or sepsis, the blood-brain barrier can be compromised. As a result, these inflammatory cytokines can cross the blood-brain barrier and affect brain function. It has been noted that encephalopathy is very common in septic patients. In fact, up to 70% of bacteremic patients have been found to have neurologic derangements.¹⁴

Although a final common pathway for delirium has not yet been elucidated, it is clear that alterations in neurotransmitters, oxidative stress, and inflammation are all related to the development of delirium. As research in this area progresses, hopefully, we will have a better understanding of the pathophysiology of this disorder. This will allow for more selective prevention and treatment of delirium.

It may be that various types of delirium—that is, hyperactive (agitated), hypoactive, or mixed—may be due to different factors in the brain. Perhaps this is why a unifying theory of delirium has not yet been established.

CLINICAL PRESENTATIONS OF DELIRIUM

Disorganized thinking, reduced attentiveness, and rambling, irrelevant, or incoherent thought patterns normally characterize delirium. The delirious patient cannot integrate a coherent stream of thoughts and deduce meaningful information from them. Short-term memory is impaired due to a short attention span and perceptual misregistration of incoming stimuli. Memory retention is also defective. A majority of delirious patients will be amnesic following recovery or will preserve small, random “islands of memory.” Fluctuating levels of arousal over the day’s course is a central hallmark of delirium and a major diagnostic criterion. The manifestations of delirium associated with sleep/wake cycles (e.g., disorganized cognitive and attention pat-

terns) fluctuate in reverse day-night cycles. Poorly organized delusions and hallucinations, as well as the presence of lucid intervals, are virtually diagnostic of stress-induced delirium. This symptomatology effectively differentiates it from dementia, functional psychosis, and dissociative psychogenic states.

During the state of delirium, cognition loses its clarity and goal direction. The patients are unable to reason deductively or solve problems and cannot perceive reality, even with direction from an unaffected onlooker. Since delirious patients cannot re-fit the fragments of cognition, their perceptions are altered, leading to the development of delusions and hallucinations. These delusions tend to be individualized and paranoid (i.e., patients misinterpret the actions and events around them as life threatening and potentially harmful). Hallucinations are characteristically fleeting, changeable, and poorly organized. Patients exhibiting this stress-induced ICU delirium continually resist restraints and treatment modalities, sometimes to the point of exhaustion. Since this psychomotor agitation syndrome usually occurs during the night hours, it has been termed the *sundown syndrome* and is virtually diagnostic of stress-induced delirium.

Organic etiologies for altered mental status, especially sepsis, must be ruled out concurrently with screening for delirium. One of the most common causes of altered mental status in the ICU is sepsis. In fact, encephalopathy from sepsis occurs in 50%-70% of patients.

The gold standard for diagnosing delirium in a patient is not necessarily an evaluation of DSM-5 criteria by a psychiatrist. Psychiatric consults usually deal with psychosis in an outpatient or low-acuity inpatient setting. The experience of psychiatrists with ICU patients may be limited, especially if the patients are intubated or poorly responsive.

Screening for delirium in all patients is helpful for understanding its prevalence and evaluating responses to treatment. The two most validated screening tools for ICU populations are the confusion assessment method for the intensive care unit (CAM-ICU) and the intensive care delirium screening checklist (ICDSC).

The CAM-ICU scale begins with an assessment of the level of consciousness using the Richmond Agitation-Sedation Scale (RASS) or the Riker Sedation-Agitation Scale (SAS)¹⁵ (Box 51-1). Both the SAS and RASS have been validated for use with the CAM-ICU.¹⁶ To examine a patient using the CAM-ICU, the RASS must be greater than -4 or the Riker greater than 2 for the patient to participate in screening.¹⁷ There are then four components to be scored: (1) acute onset or fluctuating course; (2) inattention; (3) disorganized thinking; and (4) an altered level of consciousness. The patient must have the first and second of these features combined with one of the last two (Fig. 51-1). Ideally, this scale would be used more than once during a 24-hour period to screen for delirium both during the day and at night. In the original validation studies, the CAM-ICU had a specificity of 98%-100%, sensitivity of 93%-100%, and good interrater reliability.

BOX 51-1

Richmond Agitation-Sedation Scale (RASS) Versus Riker Sedation Agitation Scale (SAS)

| RASS SCORE | TERM | SAS SCORE | TERM |
|------------|-------------------|-----------|----------------------|
| +4 | Combative | 7 | Dangerous agitation |
| +3 | Very agitated | 6 | Very agitated |
| +2 | Agitated | 5 | Agitated |
| +1 | Restless | 4 | Calm and cooperative |
| 0 | Alert and calm | 3 | Sedated |
| -1 | Drowsy | 2 | Very sedated |
| -2 | Light sedation | 1 | Unable to arouse |
| -3 | Moderate sedation | | |
| -4 | Deep sedation | | |
| -5 | Unarousable | | |

These two scales can be used to assess level of consciousness in an ICU patient.

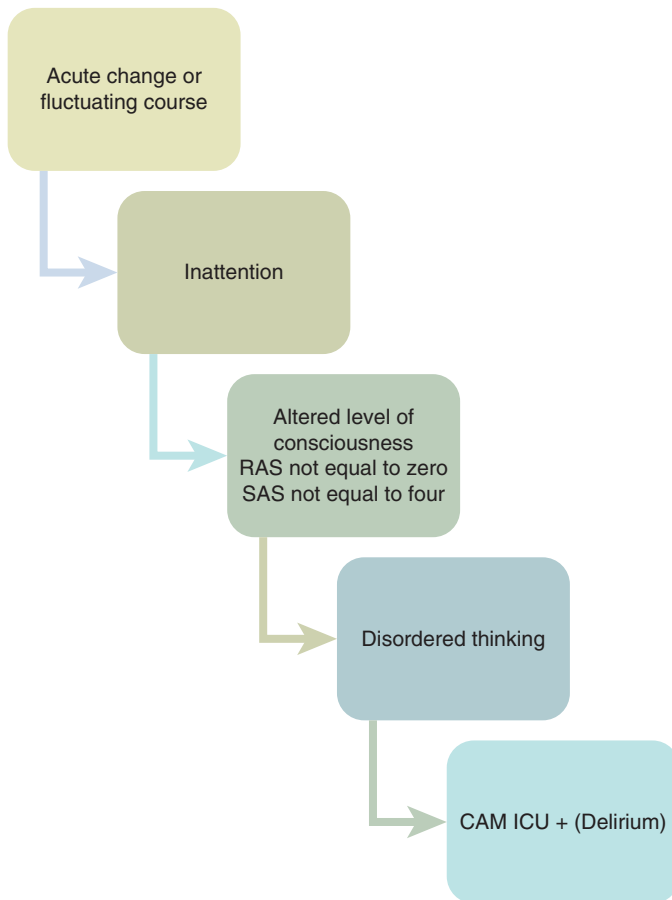

FIGURE 51-1 ■ Confusion Assessment Method for the intensive care unit (CAM-ICU). The CAM ICU screening test has multiple components that must be present to score positive for delirium. Each component has individual questions or assessments that must be positive in order to advance to the next category.

The other commonly used screening test for delirium is the ICDSC. This has eight components, which are evaluated over a 24-hour period (Box 51-2). These are derived from the DSM criteria for delirium. A score of 4 or more is consistent with a diagnosis of delirium. The original validation study demonstrated a specificity of 64% and sensitivity of 99%.¹⁸ One of the chief advantages of the ICDSC is that it evaluates patients over a 24-hour period.

Both the CAM-ICU and ICDSC are effective for the screening of delirium. A meta-analysis of studies involving these methods demonstrates a higher sensitivity and specificity for the CAM-ICU.¹⁹ Regardless of which scale is used, it is important to monitor patients for delirium throughout their ICU stay. Identifying delirious patients allows the clinician to understand the prevalence of delirium in a specific patient population and target appropriate therapeutic strategies.

■ COMORBIDITIES OF DELIRIUM

Factors that exacerbate stress in the ICU shorten the time necessary to produce delirium. These major factors contributing to the development of agitation in the ICU are pain, anxiety, and discomfort.

1. Pain: Most patients who find themselves in the ICU have had an operative or medical procedure that results in pain. The perception of pain exacerbates agitation by stimulating the sympathetic centers in the brain, resulting in catecholamine release. The hormonal

BOX 51-2 Intensive Care Delirium Screening Checklist

COMPONENTS

Altered level of consciousness
Inattention
Disorientation
Hallucination, delusion, or psychosis
Psychomotor agitation or retardation
Inappropriate speech or mood
Sleep/wake cycle disturbance
Symptom fluctuation

Scoring for the ICDSC is performed by the clinician during a 24-hour period of observation. The eight components are individually scored either zero or one. A total of four or greater is necessary to diagnose delirium.

response to pain results in sodium and water retention, due to the secretion of ADH and aldosterone, and hyperglycemia from increased cortisol and epinephrine secretions. In addition, pain also manifests by the easily recognizable triad of tachycardia, tachypnea, and systolic hypertension, all of which are amenable to ICU monitoring.

2. Anxiety: Many factors contribute to the experience of anxiety, including the fear of death or disability, misunderstanding of information provided by staff, discomfort, and the restricted ability to perform daily activities. These factors may also be associated with feelings of helplessness and loss of control. In the ICU environment, anxiety may be characterized by hyperactivity or withdrawal and may not necessarily precipitate a catecholamine response. Anxiety may rapidly progress to delirium, especially in elderly patients who have a decreased ability to cope with unusual stress.
3. Discomfort: Patients forced to lie still for long periods encumbered by indwelling hardware soon become profoundly uncomfortable and seek more comfortable positions. The need to move about and stretch can become an obsession, especially during sleepless nights, which decreases the patient's ability to cope. Sympathetic stimulation does not necessarily occur, but constant musculoskeletal activity may cause physical exhaustion.

DELIRIUM TREMENS AS A MODEL FOR SEVERE AGITATION

Beverages containing the short-acting central nervous system depressant ethanol are commonly imbibed throughout the world. The majority of those enjoying those drinks have a "stop order" switch in their brain that tells them when they have had enough. However, another population of drinkers has no such switch, or it is defective.

This population has the propensity to drink continuously, bathing their brain in a continuous flow of ethanol. This is remarkably separate from "alcoholics," whose addiction commonly presents as social problems rather than the amount of ethanol they imbibe. Alcoholics are the same whether they frequently drink, binge drink, or do not drink at all for long periods.

The brain function of an alcoholic becomes dependent on the depressive effects of ethanol, and the appropriate neuroreceptors are downregulated. Once dependence occurs, the effect extends to other chemical CNS depressants with similar actions to ethanol, particularly benzodiazepines and barbiturates. This is termed *cross-tolerance*. As one becomes dependent on ethanol, one also becomes dependent on other similar drugs.

Withdrawal from ethanol, manifested by the sudden cessation the drug, frequently as a result of trauma and resultant hospitalization, affects the downregulated neuroreceptors. Since ethanol is a short-acting drug, the receptors quickly and sometimes violently upregulate in an unregulated fashion, causing the typical scenario of agitated delirium.

The most aggressive and feared complication of ethanol withdrawal is delirium tremens (DT), a dangerous and potentially lethal syndrome of hyperactive musculoskeletal activity, hypertension, and tachycardia.

Symptoms of DT result from a compensatory increase in the activity of excitatory mechanisms, the neurotransmitters norepinephrine and dopamine, as well as the *N*-methyl-D-aspartate (NMDA) receptor, and diminished activity (downregulation) of the inhibitory receptors γ -aminobutyric acid (GABA)-A and α 2-adrenoceptors after prolonged depression of the CNS by ethanol. It has been hypothesized that physical withdrawal signs (e.g., tremor, hypertension, tachycardia, and autonomic hyperactivity) are determined by the degree of physical dependence developed during the most recent drinking period. In contrast, the psychotic signs (e.g., misperceptions, hallucinations, and seizures) result from accumulated CNS hyperactivity developed over many years of repeated alcohol intoxication and withdrawal.

Once it develops, DT is manifested by an unpredictable and volatile clinical course of agitation. Because of the phenomenon of cross-tolerance, conventional approaches utilizing sedatives (e.g., benzodiazepines and barbiturates) may require a high dosage regimen, which can precipitate hemodynamic and ventilatory depression well before the physiologic manifestations associated with delirium can be brought under control.

Ethanol withdrawal symptoms can be ameliorated with similar, but more predictable, longer acting cross-dependent CNS depressant drugs, restoring brain equanimity. Substituting cross-tolerant drugs to reset neurotransmitters does not proceed quite as effectively as the original drug (ethanol), usually requiring higher doses.

Frequently, hospital house staff choose first-generation benzodiazepines (e.g., chlorthalidoxepoxide and diazepam) for the treatment of ethanol withdrawal because of previous therapeutic recommendations. However, these drugs have been effectively superseded by second- and third-generation sedatives that are more titratable and have fewer long-acting intermediaries.

The first course of action should be the administration of a cross-tolerant sedative, in doses titrated to achieve control of the patient with a minimum of respiratory or hemodynamic side effects. As the severity of DT progresses, titratable medications are required to adjust the levels of sedation to the state of CNS excitation.

Lorazepam is an intermediate to a long-acting benzodiazepine with typical anxiolytic and sedative qualities. The drug has a mild amnesic effect as well. A dose of 4 mg of lorazepam is about equivalent to a dose of 10 mg of diazepam. Intermediary products do not accumulate, and metabolism does not require hepatic oxidation; it only requires glucuronidation, which makes it an attractive drug in liver insufficiency.

Midazolam is relatively water soluble compared with other benzodiazepines, increasing the rapidity of its action. The potency of midazolam is about three to four times that of diazepam, and it has a shorter elimination half-life of 1.5-3.5 h. Sedation following intravenous injection is achieved within 1-5 min, with a duration of less than 2 h.

Clonidine is an α -2 agonist that reduces the heart rate and hypertension, adding to a mild sedative effect. Typically, it is used as a third-line drug for DT because, while readily available in Europe, the IV formulation is not available in the United States.

Dexmedetomidine is an α -2 agonist similar to clonidine but with fewer side effects and is available in an intravenous formulation. Clinical evidence suggests that the use of intravenous dexmedetomidine may exert a beneficial sedative effect and minimal undesirable side effects in selected patients with hypertension and tachycardia as a result of severe agitation syndromes. Cardiac function and hemodynamics may improve as a result of the administration of this drug alone or in combination with attenuated doses of analgesics (e.g., morphine) or sedatives (e.g., midazolam).

There is a risk of bradycardia and/or hypotension during the administration of intravenous dexmedetomidine. However, this is a

small risk for the patients with DT as they are usually hypertensive and tachycardic when treatment commences.

Propofol is a rapid-acting, highly titratable sedative and anesthetic uniquely practical in the ICU environment because its rapid-acting and short-duration properties allow its use as a continuously titrated infusion for severe agitation in intubated patients. Propofol is indicated if the patient is out of control on high-dose benzodiazepines and if the respiratory and hemodynamic effects create hemodynamic and respiratory instability. The patient is intubated, and the treatment with propofol and short-acting beta-blockers is usually effective.

TREATMENT OF DELIRIUM

1. Treatment of stress-induced delirium: Somatosensory stress and confinement can alter delicate brain chemistry. These alterations translate into bizarre and frightening perceptions about one's environment, usually inducing paranoid ideation. From the patient's point of view, the logical course of action in such cases is to escape the perceived harm, but it is difficult to escape the encumbrances of an ICU bed. Therefore, patients exhibiting ICU psychosis continually resist restraints and treatment modalities, sometimes to the point of exhaustion. Appropriate treatment for this state is a neuroleptic medication (e.g., haloperidol), which antagonizes the D2 receptors. Haloperidol also suppresses spontaneous movements and complex behavior that result from disharmonious brain function, with a minimal CNS depressive effect. Haloperidol produces less sedation than phenothiazines, with very little effect on heart rate, blood pressure, and respiration. Despite the widespread clinical use of haloperidol, it has not been shown to reduce delirium length or severity. Atypical antipsychotics may be better at controlling delirium with fewer side effects, but this has not been well established.

Adverse hemodynamic effects are rare in healthy individuals with typical or atypical antipsychotics. Currently, the IV haloperidol dosage is not "approved" by the FDA, but the drug is commonly given by this mode and there has been a broad range of experience with it in the peer-reviewed medical literature. The dose and frequency of administration are dependent on the degree of agitation and, to a lesser extent, the patient's age.

2. Treatment of pain: There have been major advances in the understanding of pain physiology over the past decade. Earlier concepts of a dedicated, simple, spinothalamic pain system are no longer tenable. Much evidence now exists that very complex neural connections involving diverse areas of the nervous system play a part. Pain may be modulated or edited at the spinal cord level, in the periaqueductal gray matter, and brainstem raphe nuclei prior to reaching relays and gating mechanisms in the thalamus on the way to the cerebral cortex. Normally, agitation caused by pain is treated by analgesics or analgesic sedatives (e.g., morphine sulfate). This class of medications ultimately diminishes the stimulus to secrete epinephrine and norepinephrine and so decreases the end organ response to these catecholamines. Agitation syndromes resulting from pain usually resolve when the primary stimulus disappears. Humoral responses of patients in pain (e.g., hypertension and tachypnea) tend to counterbalance the side effects of narcotic analgesics (e.g., hypotension from histamine release and medullary ventilation center depression). The synthetic narcotic fentanyl provides good analgesia and sedation with reduced histamine-related side effects. The parenteral NSAID ketorolac provides pure analgesia with no sedation when the side effects of narcotics are unwelcome.
3. Treatment of anxiety and discomfort: Numerous authors recommend that anxiolytic medications be used routinely in the ICU. Benzodiazepines have been the mainstay of ICU anxiety treatment for many years because they offer a wide margin of safety from unwanted side effects. Their exact mode of action is unknown but appears to be within the limbic system via the neuroinhibitory transmitter gamma aminobutyric acid (GABA). In addition to their

sedative qualities, benzodiazepines have actions that promote anxiolysis, anterograde amnesia, hypnosis, and skeletal muscle relaxation. Patients confined to an ICU bed may not be experiencing much pain but are more likely uncomfortable and seeking a way to relieve muscle cramps and aches. Benzodiazepines are effective as CNS depressants that decrease the perception of discomfort and the resulting anxiety. Benzodiazepines with short half-lives (e.g., midazolam) are especially useful when an hour-to-hour titration is required for patients with unstable hemodynamics. Lorazepam is useful when a longer acting sedative is required for longer term sedation as it has minimal hemodynamic side effects. Lorazepam is also useful in a continuous infusion for long-term sedation. Dexmedetomidine or propofol can also be administered as continuous infusions to assist with anxiety.

Preferred Routes of Administration for Sedatives

The intramuscular absorption of drugs is influenced by the ratio of the ionized to unionized drug, site of injection, blood flow to the site region, and the amount of drug metabolized before entry into the systemic circulation, all of which are variably affected by critical illness. Intramuscular injection typically requires musculoskeletal activity and adequate tissue perfusion to enhance absorption into the systemic circulation. Since patients in the ICU usually lie still, they tend to absorb drugs from the muscles erratically. ICU patients also frequently suffer from decreased tissue perfusion because of varying degrees of heart failure and multiorgan insufficiency, which also decrease the reliability of muscular absorption.

In the ICU, medications are generally administered intravenously. The intravenous administration of sedatives offers the advantage of close titration, a very big plus in the treatment of unstable patients. Insertion of central venous access is usually indicated to ensure that the drug continues to have access to the central circulation as peripheral IVs may infiltrate with very little warning, particularly in the middle of the night. Intraarterial catheters are indicated for constant blood pressure monitoring and easy access for blood sampling.

Most rapidly acting drugs (e.g., midazolam) are highly water soluble and can only be titrated by intravenous administration. However, the effective titratability of these drugs likely decreases with time as the volume of distribution throughout the body water compartments increases. Organ insufficiency, particularly liver failure, also decreases the short-term titratability of most sedatives by prolonging the serum half-life.

Continuous infusions of analgesics and sedatives are a very effective method of avoiding the “valleys” inherent in bolus medication therapies that initiate a “peak” of therapeutic action followed by a variable period of “valley” in which the patient has little or no drug effect. The current literature suggests that high-risk cardiac patients are jeopardized by relatively brief periods of analgesia ineffectiveness.

Intermittent periods of sympathetic stimulation due to ineffective analgesia and sedation can cause relatively profound deleterious effects on the compromised myocardium. Continuous intravenous infusions of short-acting agents such as midazolam, propofol, and fentanyl allow for a titration of the plasma level effects to a fluctuating baseline of pain, anxiety, and discomfort. This real-time titration of natural fluctuations may occur with minimum hemodynamic and respiratory suppression.

Pitfalls in the Treatment of Delirium in the ICU

1. Treatment of stress-induced delirium with inappropriate medication: Treating psychotic delirium with analgesic sedatives is ineffective and deceiving. These patients are usually not in pain and do not necessarily manifest excess circulating catecholamines. Therefore, the analgesic effect of morphine is lost, and the predominating effect remains that of hemodynamic and ventilatory suppression. Therefore, psychosis remains in the face of compro-

mised hemodynamics and ventilation, requiring the addition of additional monitoring technology with the potential for increased stress and agitation.

The treatment of psychotic delirium with CNS depressants (e.g., benzodiazepines) confuses the border between psychosis and organic brain dysfunction. In addition, benzodiazepines have no ability to reorganize aberrant brain chemistry; therefore, psychotic patients treated with sedatives simultaneously become more obtunded and confused, further obfuscating the treatment plan.

2. Treatment of pain with inappropriate medication: Attempts to avoid morphine's hemodynamic side effects by using benzodiazepines as analgesics are usually ineffective. The hemodynamic effects of benzodiazepines are minimal compared to morphine, but they do not significantly attenuate the humoral responses to pain. In fact, benzodiazepines superimpose a cloud of CNS depression over pain stimuli, producing the appearance of comfort but no actual analgesia. The patient may appear more comfortable but still has hypermetabolic humoral responses that continue unabated, ultimately causing end organ damage or dysfunction.

Neuroleptics (e.g., haloperidol) promote no analgesic effect and a sedative effect only in large doses in which side effects predominate. Attempts to treat agitation resulting from pain by antipsychotic neuroleptics superimpose bizarre neurologic side effects on top of pain responses. The issue may be further confused by bizarre CNS symptoms additive to the normal humoral response of catecholamines. The patient may then feel “weird” but still in pain, and agitation may increase as the patient's attempts to make sense of a distorted world.

3. Treatment of anxiety and discomfort by inappropriate medication: Attempts to ameliorate discomfort with analgesic sedatives (e.g., morphine) are frequently effective, but these drugs produce hemodynamic side effects. Patients who are uncomfortable often have a little pain and thus few attendant humoral catecholamine effects. Therefore, the side effects of narcotics (e.g., hypotension and respiratory depression) predominate. Patients with a compromised cardiorespiratory status tolerate these side effects poorly and may not benefit from the analgesic effects, even in low doses. The patient may appear more comfortable but will ultimately require additional monitoring devices applied to proctor the hemodynamic side effects, increasing discomfort and agitation.

Patients who are uncomfortable are not necessarily psychotic. The sedative actions of haloperidol are attenuated except in high doses, which may exaggerate the CNS side effects. The patient may struggle more in an attempt to escape the frightening CNS side effects. Since sedation is achieved only with high doses, the extrapyramidal side effects may also be expressed.

It is currently recommended that narcotics be first titrated to any pain, and then afterward sedative medications can be used as needed. Sedative medications should be avoided if possible.²⁰

PREVENTION OF DELIRIUM

There has been great interest in preventing patients from developing delirium. Not only would this likely reduce patient morbidity, but primary prevention also may be able to reduce the health care costs for the treatment of delirium and its complications. There are two main approaches to prevention of delirium: nonmedication- and medication-related therapies.

Nonpharmacologic strategies for delirium can manifest in several forms. ICU clinicians should encourage patients to maintain a normal sleep/wake cycle. This includes minimizing the lights and noise during the nighttime hours. Frequent reorientation to the day and time is often helpful. The presence of family members at the bedside can be reassuring to the patient and assist in the reorientation to place and time. Eyeglasses and hearing aids should also be provided to patients if normally used at home. Despite a lack of good-quality evidence supporting these interventions, they are relatively easy to perform at no cost to the health care system.

More aggressive interventions to prevent delirium have also shown some promise in clinical trials. A prospective trial of a multifaceted program in patients greater than 70 years old was successful in reducing delirium rates (9.9 vs. 15.0%, $P = 0.02$).²¹ This intervention targeted six risk factors: cognitive impairment, immobility, disordered sleeping, dehydration, and visual and hearing impairments. The cost of such a program is significant with regard to personnel and time requirements. This limits the ability to scale such a set of interventions.

Early mobility may be a potential method to reduce the incidence of delirium. Mobilizing ICU patients early has many benefits, including reduced ICU and hospital length of stay, more ventilator-free days, and fewer sedation requirements.^{22,23} It has even been shown to reduce the use of physical restraints, which has been associated with increased delirium.²⁴ In addition to these positive outcomes, the delirium length was reduced as well.

Prophylactic medication therapy for delirium has been studied to a limited degree. The majority of the evidence is conflicting and does not exhibit a clear benefit to prophylaxis.²⁵ The Society of Critical Care Medicine published guidelines that do not currently recommend any medication to prevent delirium. Antipsychotic medications may have some benefit for postoperative patients, but it is not clear if this is universally true for ICU patients.²⁶ Furthermore, there are definite risks to antipsychotic medications, particularly QT prolongation and subsequent torsades de pointes that preclude their widespread use.

Dexmedetomidine, a highly selective alpha2-adrenergic receptor agonist, has been suggested as a possible medication that may reduce the risk of developing delirium.²⁷ However, it is not clear if the use of dexmedetomidine prevents delirium or is simply less likely to cause it compared to more commonly used sedative medications. Propofol and dexmedetomidine likely reduce the duration of mechanical ventilation compared with benzodiazepines and ICU length of stay, but this does not necessarily translate into a lower risk of delirium.²⁸

There has also been great interest in cholinesterase inhibitors for the prevention of delirium. This is based on the proposed mechanism of abnormally low levels of acetylcholine in delirium. This has not been well studied at this point, but there has not been any clear evidence to support the prophylactic use of cholinesterase inhibitors.²⁹

Certain medications may be associated with higher delirium rates. Opioids and benzodiazepines may increase the risk of delirium, but the data are extremely conflicting. Withdrawal from alcohol and benzodiazepines can be associated with delirium. In addition, glucocorticoids, anticholinergic medications, and histamine-2 receptor antagonists can cause delirium.⁹ From a practical standpoint, it is unlikely that the clinician will be able to completely avoid medications

that can induce delirium. However, it is important to have an appreciation that some medications may cause delirium in susceptible patients. In these cases, it would be best to avoid triggering medications if possible.

LONG-TERM OUTCOMES

Delirium is a disorder that extends beyond the ICU course. Moreover, it is a risk factor for an extended length of stay in the ICU, as well as the hospital and has been associated with increased mortality. Patients who are delirious often require additional attention from ICU staff to prevent them from hurting themselves or others. In addition, patients who experience delirium are often restrained and given additional sedative medication that may lead to intubation. These extra interventions and therapies have the potential to cause harm and increase medication side effects. Family members find delirium in their loved ones to be deeply disturbing. The sudden changes in personality and affect can be difficult to understand when families are already facing serious and often new medical diagnoses.

It is important to diagnose properly, prevent, and treat delirium in ICU patients to avoid unnecessary morbidity and mortality. This is a remarkably common disorder among all types of ICU patients. Those who work in an ICU should be aware of the dangers of delirium and actively seek to reduce its occurrence.

KEY POINTS

1. Delirium is a disorder characterized by fluctuating or acute changes in mental status, coupled with inattention and disorganized thinking.
2. Many patients experience delirium in the ICU. It can increase hospital/ICU length of stay and mortality.
3. Some strategies for preventing delirium include frequent reorientation, avoiding delirium-inducing medications, and mobilizing patients.
4. Delirium is difficult to treat. The clinician should focus on adequate pain control and antipsychotic medications if needed while avoiding oversedating patients.
5. Severe ethanol withdrawal can result in delirium tremens. This can be treated with sedative infusions.

Stroke is currently recognized as the fifth most common cause of death and the leading cause of permanent disability in the United States, affecting nearly 795,000 people annually.¹ Acute ischemic stroke is a true medical emergency and must be treated with a swift yet pragmatic approach. The rationale for acute ischemic stroke treatment is based on the concept of the *ischemic penumbra*. When arterial occlusion occurs, an area of irreversibly infarcted brain (i.e., core infarct) is surrounded by a region that has reduced blood flow that impairs function (i.e., ischemic penumbra), although not of sufficient severity to result in irreversible infarction. If adequate blood flow can be restored within a critical time frame, this area of at-risk tissue may be salvageable and return to normal function. The relationship between blood flow levels and duration for human stroke is still being elucidated, but based on laboratory studies, the more quickly restoration of blood flow occurs, the greater the probability that the salvageable tissue will be spared from permanent damage.^{2,3}

In 1995, the National Institute of Neurological Disorders and Stroke (NINDS) rt-PA Stroke Study Group showed for the first time an improvement in ischemic stroke outcome with acute treatment.⁴ At present, intravenous tissue plasminogen activator (t-PA) is the only treatment that has been approved by the Federal Drug Administration (FDA) for acute ischemic stroke patients presenting within 3 hours of symptom onset. Intraarterial therapy with stent retriever thrombectomy should be considered in patients presenting with acute ischemic stroke within 6 hours of symptom onset.⁵ Other treatments for acute ischemic stroke, such as neuroprotective agents and cell replacement therapy, continue to be investigated.

EMERGENT STROKE EVALUATION

For patients in the field who develop symptoms concerning for acute ischemic stroke, once emergency medical services (EMS) are activated, a rapid neurologic assessment is performed using one of several pre-hospital stroke scales. These quick screening tools allow uniformity in assessing stroke deficits that clarify communication of the patient's status to the receiving emergency department. It is helpful if pre-hospital personnel are able to firmly establish with family or bystanders who witnessed the patient's symptom onset the precise time at which the patient last appeared normal. Upon arrival, or more ideally, before arrival at the emergency department, a "brain attack code" or "stroke code" is disseminated to members of the stroke team.

A stroke team typically consists of individuals from multiple disciplines with specialized knowledge and interest in acute stroke care and often includes a vascular neurologist, nursing coordinator, and where available, a neuro-interventionalist. A neurologist performs a National Institutes of Health Stroke Scale (NIHSS) (Table 52-1) assessment as an additional rapid neurologic assessment tool to better localize and ascertain the degree of clinical deficit, as the score may affect which therapies are available to the patient. For patients developing focal neurologic symptoms while already hospitalized in an intensive care unit (ICU) or other hospital floor, the algorithm should be identical.

Ischemic strokes generally are classified as large artery atherosclerosis, small vessel occlusion, cardioembolism, stroke of other determined etiology, or stroke of undetermined etiology.⁶ In the first few minutes to hours after ischemic stroke, identification of stroke mechanisms may be difficult or impossible. Emergent diagnosis is greatly

enhanced by imaging modalities, including computed tomography (CT) and magnetic resonance imaging (MRI).

IMAGING OF ACUTE STROKE

Differentiating ischemic from hemorrhagic stroke is necessary before deciding on thrombolytic administration, and imaging obviously plays a key role in this regard. However, imaging may provide much more information. At most stroke centers, time from symptom onset (i.e., time when patient was last confirmed to be seen at normal baseline) is a major determining factor in whether a patient is a candidate for intravenous thrombolysis (up to 3 hours) or intraarterial therapy (up to 6 hours). An emerging concept is that physiology rather than time should be used to decide on treatment eligibility.⁷ For example, some patients within the 3-hour time window may already have established infarction that would not reverse with thrombolysis and may result in hemorrhage owing to reperfusion of infarcted brain. Conversely, some patients may have salvageable brain tissue despite presentation well after the 3-hour time window. A physiologic estimate of tissue viability would be preferable to a fixed time interval if a study were found that reliably predicted viability of brain after stroke. CT and MRI have the potential to provide this measurement.⁸

Computed Tomography

A noncontrast head CT is the initial imaging modality of choice for patients with suspected stroke. The foremost reason is that CT scans can be readily and quickly obtained because of the widespread availability of CT scanners; the second reason is the ability of CT to exclude intracranial hemorrhage. In addition to differentiating ischemic stroke from hemorrhage, CT may demonstrate subtle parenchymal abnormalities indicative of early edema or infarction. Previously, it was believed that these changes did not occur on CT for at least 6 hours after ischemic stroke. More recent studies indicate, however, that early changes of ischemia frequently occur within a few hours of stroke onset and have been seen as soon as 1 hour after stroke.⁹ These changes include reduced attenuation in the basal ganglia,² loss of gray-white differentiation, particularly in the insular region,¹⁰ low density in the cortex and subcortical white matter, and loss of sulcal markings suggesting early mass effect and edema (Fig. 52-1, A and B).¹¹

A hyperdense middle cerebral artery occurs in 20% to 37% of cases,¹² indicating acute thrombus within the artery. This condition rarely occurs without at least one other early CT abnormality. Hyperdensity in the basilar artery associated with thrombosis also has been reported.¹³ In 100 patients studied within 14 hours (mean 6.4 hours) of stroke onset, multiple early CT abnormalities correlated with the size of the subsequent infarct and poor outcome.¹² In the ECASS I trial of t-PA for acute stroke, early CT changes correlated with larger subsequent infarct volume and a greater likelihood of hemorrhagic conversion after t-PA.¹⁴ Quantitative assessment of CT changes using the Alberta Stroke Program Early CT Score (ASPECTS) scale in patients treated with intravenous t-PA also showed a relationship between early CT hypodensity (ASPECTS <8) and hemorrhage.^{15,16} Thus, some experts recommend withholding thrombolytic therapy in patients with extensive early CT changes, particularly in those later in the thrombolytic time window,¹⁷ although this practice is controversial.

TABLE 52-1 National Institutes of Health Stroke Scale

| | | |
|---|---|--|
| 1A. LEVEL OF CONSCIOUSNESS (LOC) 0 = Alert 1 = Not alert, but arousable 2 = Not alert, obtunded 3 = Coma | 1B. For example, subsequent analysis of the NINDS rt-PA trial data revealed that early ischemic changes did not predict symptomatic hemorrhage or response to treatment,¹⁸ and more recent evidence reports no association between early ischemic CT changes and outcome.¹⁹

Computed Tomography Angiography

CT angiography (CTA) can be performed using spiral CT, allowing for imaging of the intracranial and extracranial circulation. Optimally, CTA of the neck should also include visualization of the aortic arch. The typical single bolus of iodine contrast material is about 70 cc. This injection limits the use of CTA in patients with renal failure or contrast hypersensitivity. In acute stroke, CTA of the head and neck is highly reliable for diagnosis of intracranial occlusions and correlates with other imaging modalities.^{20,21} Three-dimensional reconstruction images can also be created, providing additional views and information about the carotid bifurcation and carotid lesions, revealing eccentric lesions and ulceration (Fig. 52-1, C and D).

Computed Tomography Perfusion

In addition to imaging the brain parenchyma with a noncontrast head CT and the cerebral vasculature with CTA, CT perfusion (CTP) adds assessment of cerebral blood volume (CBV) and cerebral blood flow (CBF) (Fig. 52-2). In patients with acute stroke, CTP has been correlated with final infarct size and outcome, particularly after recanalization.²² CTP maps combining CBV and CBF identify brain tissue that progresses to infarction if not reperfused, consistent with ischemic penumbra.²³ Recent evidence suggests that the inclusion of CTP in a stroke imaging protocol increases diagnostic performance.^{22,24,25}

Whereas CTP serves as a qualitative measure of CBF, there have been investigations into using xenon CT to measure CBF quantita-

tively.²⁶ Stable xenon is an inert gas inhaled as a mixture of 27% xenon and 73% oxygen. During inhalation over a few minutes, rapid scanning is performed, and pixel-by-pixel blood flow values are calculated at different brain levels (Fig. 52-3). In a series of patients with middle cerebral artery (MCA) occlusion studied with xenon CT, areas of penumbra were present in all patients, and the percentage of MCA territory in the penumbral range (CBF 8-20 mL/100 g/min) remained relatively constant across the group. In contrast, the percentage of MCA territory with CBF values representing infarcted tissue (CBF < 8 mL/100 g/min) varied greatly. Outcome correlated highly with the area of infarcted MCA territory, not the amount of ischemic penumbra. Thus, after the first few hours, the size of the core infarcted tissue, not the amount of penumbral tissue, may be the most important imaging parameter to determine suitability for acute stroke therapy.²⁷

Magnetic Resonance Imaging

Compared to CT modalities, MRI is advantageous because it is more sensitive to cerebral infarction, especially in the brainstem and deep white matter. Typical sequences included in an MRI stroke protocol include diffusion-weighted imaging (DWI) and apparent diffusion coefficient (ADC) to evaluate for potential acute ischemia, multiplanar gradient-recalled (MPGR) or gradient-recalled echo (GRE) to evaluate for hemorrhage, and fluid-attenuated inversion recovery (FLAIR) to evaluate for important signs in both hyperacute and acute stages of stroke (i.e., assessment for absence of flow void in major cerebral arteries, suggesting occlusion or slow flow in that artery). Perfusion-weighted imaging (PWI) is often used to determine abnormal tissue perfusion based on transit times for contrast material through brain parenchyma (Fig. 52-4).

DWI shows parenchymal abnormalities earlier than conventional T2-weighted images in patients with acute stroke.²⁸ DWI detects the

FIGURE 52-1 ■ **A**, Normal computed tomography (CT) scan of brain 2 hours after onset of aphasia and left hemiparesis. **B**, Repeat CT scan at 5 hours after stroke onset shows early CT changes, including basal ganglia hypodensity, loss of the insular ribbon, and slight effacement of the sulci on the left. **C**, CT angiogram at 5 hours after stroke onset shows complete occlusion of the left middle cerebral artery. **D**, Rapid reconstruction of the CT angiogram again shows occlusion of the left middle cerebral artery.

FIGURE 52-2 ■ Computed tomography brain perfusion scan with sequencing maps. **A**, Cerebral blood volume (CBV) showing no clear evidence of core infarct. **B**, Cerebral blood flow (CBF) showing a decrease in the right middle cerebral artery (MCA) territory. **C**, Mean transit time (MTT) showing delayed perfusion in the right MCA territory. These sequences together indicate a large ischemic penumbra in the right MCA territory.

FIGURE 52-3 ■ Xenon computed tomography blood flow study from a patient with a large left hemisphere stroke 3 hours after onset of symptoms. Flow is nearly absent throughout the middle cerebral artery territory on the left.

FIGURE 52-4 ■ Magnetic resonance imaging of the same patient in Fig. 52-2. **A**, Diffusion-weighted imaging (DWI) showing right basal ganglia stroke. **B**, Perfusion-weighted imaging (PWI) showing enhanced mean time to enhancement. These sequences together suggest a large ischemic penumbra in the right MCA territory.

diffusion of water in the brain and shows hyperintensity in areas of reduced diffusion (Fig. 52-4). As water moves from the extracellular to the intracellular space, there is less movement of water and loss of signal, resulting in hyperintensity.²⁹ Early detection of lesions by DWI helps differentiate cerebral ischemia from other conditions that mimic stroke, such as seizures or toxic-metabolic states. Additionally, combining DWI with PWI may identify reversibly ischemic tissue. If there is a large area of PWI abnormality indicating reduced CBF but limited established infarction as evidenced by DWI abnormality, penumbral tissue is likely present, indicating areas at risk of undergoing infarction.

In stroke patients, the size of the DWI lesion and the growth of these abnormal DWI regions are strong predictors of outcome. In acute stroke, a marker of tissue viability is needed, and some investigators

have suggested that the extent of mismatch between lesions on DWI and PWI could serve as this marker. The concept of DWI/PWI mismatch has been used as an inclusion criterion in several studies (DIAS, DIAS-2, among others) assessing thrombolytic agents and is being employed more frequently to select patients who may benefit from reperfusion therapy.³⁰⁻³⁷ Patients with mismatch might be more likely to respond to reperfusion therapy.³⁸ Patients with large areas of DWI abnormality or large severe PWI abnormalities may be at greater risk for hemorrhage if reperfusion therapy is pursued.³⁹

Magnetic Resonance Angiography

MRA of the head and neck offers a noninvasive method of imaging the intracranial and extracranial vasculature. MRA typically uses

gadolinium contrast in appropriate patients, but important information can be obtained based on time-of-flight techniques not utilizing contrast.^{40,41} Detection of dissection or occlusion in the circle of Willis and the extracranial vertebral and carotid arteries can be examined with MRA, but occlusions of small peripheral branch arteries may not be detected. Artifacts may also obscure proper identification of arterial pathology. Signal dropout may occur at the site of arterial stenosis owing to the effects of turbulent flow. If an artery is tortuous, it may extend out of the imaging section and appear occluded. MRI tends to overestimate the severity of stenosis, and evidence of severe stenosis should be confirmed with another modality. MRA is better for localizing the site of stenotic lesions than determining severity of stenosis. Similarly, differentiation between severe stenosis and occlusion is unreliable with MRI, and apparent occlusions by MRA should also be confirmed with angiography.

Digital Subtraction Angiography

Catheter-based digital subtraction angiography (DSA) remains the gold standard for determining the degree of vessel stenosis and understanding the collateral circulation. The high quality of anatomic delineation allows for precise determination of carotid stenosis as CTA, whereas MRA and carotid Dopplers can misclassify stenosis. Historically, the procedure has been associated with a high risk of complications, although more modern experience estimates a much lower risk of stroke (0.3%) at experienced centers.^{42,43} The technique requires specialized personnel and equipment and may not be readily available at centers.

TREATMENT OF ACUTE STROKE

Intravenous Thrombolysis

Acute stroke trials using intravenous thrombolytic agents date back to the early 1960s, with the use of streptokinase,⁴⁴ fibrinolytic,⁴⁵ and urokinase⁴⁶ showing either no benefit or a higher mortality in patients treated with thrombolysis. These studies preceded CT imaging and thus patients with hemorrhage were not excluded. The discouraging results hindered the development of more acute stroke trials until the 1980s, when several case reports showed favorable outcomes with intraarterial thrombolytic therapy within a few hours of stroke onset.^{47,48} These reports resulted in small randomized trials and feasibility studies of intravenous thrombolytics^{49,50} that ultimately gave rise to the pivotal NINDS rt-PA trial that showed a beneficial effect of thrombolytic therapy for acute stroke treatment when administered within 3 hours of symptom onset.⁴

Tissue Plasminogen Activator Within 3 Hours

The NINDS trial included more than 600 patients with acute ischemic stroke. All patients were treated within 3 hours, and half of the patients were treated within 90 minutes. Patients were randomly assigned to receive either intravenous t-PA at a dose of 0.9 mg/kg to a maximum of 90 mg or intravenous placebo. Primary outcome measures were favorable outcomes at 90 days measured by the NIHSS, Barthel Index, Glasgow Outcome Scale, and modified Rankin Scale (mRS). By all four measures, significantly more patients had a favorable outcome at 90 days in the t-PA group compared with placebo. Treatment with t-PA resulted in an 11% to 13% absolute increase in good outcomes and a minor, nonsignificant decrease in mortality at 3 months. The benefit was sustained at 12 months.⁵¹ Intracerebral hemorrhage with clinical deterioration occurred in 6.4% of patients treated with t-PA versus only 0.6% of placebo patients. Despite the increased hemorrhage rate, there was no significant increase in mortality or severe disability in the t-PA group versus placebo. All subtypes of strokes had more favorable outcomes with t-PA. There were no clear factors that predicted response to t-PA.⁵² Patients with large strokes as measured by NIHSS score >20 and evidence of early low density or edema on CT had a higher rate of hemorrhage after t-PA.⁵³

TABLE 52-2

Data from The ATLANTIS, ECASS, and NINDS rt-PA Study Group Investigators. Association of outcome with early stroke treatment: pooled analysis of ATLANTIS, ECASS and NINDS rt-PA stroke trials. *Lancet*. 2004;363(9411):768-774.

Based on these results, the FDA approved intravenous t-PA for treatment of stroke within 3 hours of onset in June 1996. This result was supported by the results of an analysis of patients treated within 3 hours of onset in the ATLANTIS trial.⁵⁴ A subsequent pooled analysis of NINDS rt-PA, ECASS, and ATLANTIS data showed that clinical benefit with t-PA is greatest when given early, especially if started within 90 minutes (Table 52-2).⁵⁵ Not all patients recanalize with intravenous t-PA. In a dose escalation trial of intravenous t-PA, angiography was performed before thrombolysis in all patients documenting the site of arterial occlusion and was repeated 2 hours later. Proximal occlusions in the MCA opened less frequently than distal branch occlusions, and only 8% of carotid occlusions recanalized.⁵⁶

Given the importance of early drug administration, much attention has been placed on improving systems of care to deliver the drug early and often. The use of telemedicine has played a great and expanding role in allowing patients presenting to stroke-ready hospitals without in-house vascular neurology expertise to receive remote clinical examination and imaging review via video streaming. Within our stroke network at the University of Pittsburgh, the implementation of telemedicine at 12 neighboring hospitals increased the use of IV thrombolysis from 2.8% to 6.8%, with a lower incidence of symptomatic hemorrhage. Similar experiences have been reported across the country. Emphasis has also been placed on minimizing additional tests (i.e., coagulation profile or platelet count) in selected patients and prioritizing imaging and early stroke team activation. Campaigns to improve times have driven door-to-needle times down to 22 minutes at some centers.

Tissue Plasminogen Activator Beyond 3 Hours

Several subsequent t-PA trials attempted to extend the window for treatment beyond 3 hours. The ECASS I and II trials and the ATLANTIS trial treated patients with intravenous t-PA up to 6 hours after stroke onset but failed to show benefit versus placebo.⁵⁷⁻⁵⁹ Pooled analysis of NINDS rt-PA, ECASS, and ATLANTIS data suggested a potential benefit beyond 3 hours. The ECASS III trial recently revealed that intravenous alteplase administered between 3 and 4.5 hours after symptom onset significantly improved clinical outcomes in patients with acute ischemic stroke, thereby potentially extending the therapeutic window in which patients may receive intravenous t-PA. In addition to standard intravenous t-PA exclusion criteria (Table 52-3), ECASS III exclusion criteria include the combination of previous stroke and diabetes, an NIHSS score >25, oral anticoagulant treatment, or age >80 years.⁶⁰ Whether patients in this time window with these exclusions also benefit from intravenous t-PA is unknown.

IST-3 is a clinical trial that randomized 3035 patients with ischemic stroke within 6 hours of symptom onset to intravenous alteplase (0.9 mg/kg; n = 1515) plus standard care or standard care alone (control; n = 1520). While the primary end point of good outcome was no different between groups, the study did show improved outcomes in patients presenting within early time windows and enrolled a high

percentage of elderly patients (age > 80), thus establishing the efficacy of intravenous tissue plasminogen activator (IV tpa) in this population. Several ongoing trials are investigating a role for IV tpa in patients presenting at late time windows with favorable imaging profiles (i.e., small core and large penumbra or DWI/FLAIR mismatch).

Mild and Rapidly Improving Symptoms

While the original NINDS study considered mild or rapidly improving symptoms as a relative contraindication for IV thrombolysis, subsequent retrospective analysis of this population has revealed poor outcomes, with up to 30% to 40% of patients requiring inpatient rehabilitation at discharge and a subset suffering further neurologic decline. While the natural history in this population may not be as benign as previously perceived, the benefit of IV thrombolysis remains to be proven. A review of patients within the SPOTRIAS database revealed practice variation across centers with a range of 2.7% to 18% of mild stroke patients receiving IV tpa. Furthermore, the proportion of patients with mild NIHSS increased from 4.8% in 2005 to 10.7% in 2009 ($P = 0.001$). This degree of practice variation highlights the uncertainty in this population and has prompted the initiation of a randomized clinical trial to investigate the role of IV alteplase in mild or rapidly improving symptoms (PRISMS trial).

Other Thrombolytic Options

Desmoteplase is a recombinant form of vampire bat saliva that is more potent than t-PA. Desmoteplase possesses high fibrin selectivity, allowing it to dissolve a clot locally with less effect on the blood coagulation system. This feature may potentially reduce the risk of intracranial and systemic bleeding versus less fibrin-specific plasminogen activators like t-PA. Desmoteplase was investigated in multiple trials to determine whether it could extend the treatment window for intravenous thrombolysis up to 9 hours.^{31,33} Unfortunately, no benefit was realized between 3 and 9 hours after stroke symptom onset.³² Tenecteplase is a modified form of human t-PA designed to achieve more effective thrombolysis. The half-life of tenecteplase is longer, allowing administration as a single bolus. Similar to desmoteplase, tenecteplase has greater fibrin specificity and less fibrinogen depletion than t-PA.⁶¹ A phase IIb study randomly assigned 75 patients to receive alteplase (0.9 mg per kilogram of body weight) or tenecteplase (0.1 mg per kilogram or 0.25 mg per kilogram) less than 6 hours after the onset of ischemic stroke. The two tenecteplase groups had greater reperfusion ($P = 0.004$) and clinical improvement ($P < 0.001$) at 24 hours than the alteplase group, with no differences in intracranial bleeding or serious adverse events. The

higher dose of tenecteplase (0.25 mg per kilogram) was superior to the lower dose and to alteplase for all efficacy outcomes, including absence of serious disability at 90 days. Reteplase is another recombinant form of human t-PA shown to be effective in the treatment of acute myocardial infarction.⁶² Reteplase also possesses a longer half-life than t-PA, and a small case series found that in patients treated 9 hours after stroke onset with intraarterial reteplase, 88% completely recanalized and 44% achieved clinical improvement at 24 hours.⁶³ Intraarterial reteplase has also been studied with intravenous abciximab, a glycoprotein IIb/IIIa inhibitor, in a phase I study administering the combination therapy to stroke patients presenting between 3 and 6 hours.⁶⁴ Abciximab may direct its effect through powerful antiplatelet effects or by direct thrombolysis.

Abciximab monotherapy as emergent stroke treatment has also been evaluated in a phase 2 trial, with improved outcome at 3 months in patients with mild to moderate strokes.⁶⁵ A phase 3 trial was then initiated but stopped prematurely due to an unfavorable benefit-risk profile.⁶⁶ The Combined Approach to Lysis Utilizing Eptifibatide and rt-PA in Acute Ischemic Stroke-Enhanced Regimen (CLEAR-ER) trial showed safety of concomitant administration of r-tPA with another glycoprotein IIb/IIIa inhibitor, eptifibatide. A phase III trial is under way to compare this approach to rt-PA alone (CLEAR STROKE trial). The recently completed ARTIS trial compared alteplase to 300 mg intravenous aspirin within 90 min after start of alteplase treatment or to no additional treatment. This study was prematurely terminated at 642 patients because of an excess of symptomatic intracranial hemorrhage and no evidence of benefit in the aspirin group.

Intraarterial Therapy

Intraarterial Thrombolysis

An alternative approach to intravenous thrombolysis is direct delivery of thrombolytic agents by a microcatheter embedded in the clot (Fig. 52-5). The advantage of the intraarterial approach is direct visualization of the occluded artery and knowledge of the recanalization status as thrombolysis proceeds. Theoretically, delivery of the thrombolytic agent to the site of the clot should be more effective than intravenous infusion. The disadvantage is the additional time needed to bring the patient to the angiography suite, prepare the groin, catheterize the femoral artery, and guide the catheter from the femoral artery to the intracranial circulation before the thrombolytic agent can be administered.

Urokinase was used in early studies of intraarterial thrombolysis but is no longer available.⁶⁷ Recombinant prourokinase was evaluated formally in clinical trials,⁶⁸⁻⁷⁰ and the PROACT II study was the first acute stroke trial to show a significant improvement in outcome when administered within 6 hours of stroke symptom onset. The median time to treatment was 5.5 hours, and most patients were treated after 5 hours.⁶⁹ The clinical benefit was apparent despite this late time to treatment; a greater benefit may have been found had patients been treated earlier or mechanical manipulation also been allowed. Symptomatic hemorrhage occurred in 10% of patients treated with recombinant prourokinase and in 2% of controls. Although the hemorrhage rate was higher than previous intravenous thrombolytic studies, the median NIHSS score of 17 indicates that the patients in the PROACT II study had more severe strokes treated at a later time interval. A higher hemorrhage rate would be expected in these scenarios. There was also no differential effect of recombinant prourokinase across risk strata, indicating that all patients, regardless of risk, benefit equally from recombinant prourokinase.⁷⁰ Nevertheless, prourokinase has not been FDA approved to date, and t-PA tends to be more often used in cases of intraarterial thrombolysis. The exact dose, efficacy, and safety profile of intraarterial t-PA is limited, but recent studies have suggested doses up to 40 mg are reasonably safe for use.⁷¹

First-Generation Mechanical Devices

Although most thrombolytic studies concentrate on time to treatment, the most important factor for clinical outcome is probably time to

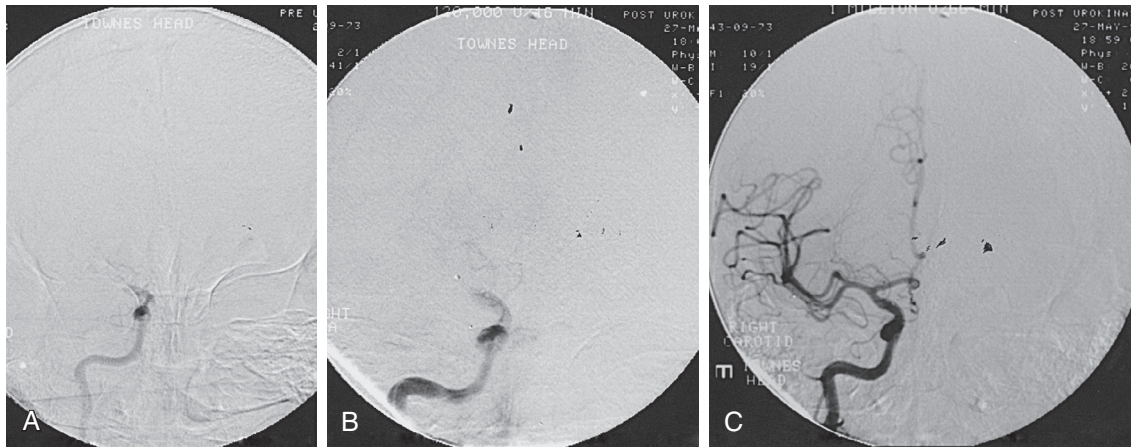

FIGURE 52-5 ■ **A**, Right carotid angiogram from a patient with embolic occlusion of the right middle cerebral artery (MCA) 4 hours after onset of symptoms. **B**, Angiogram from the same patient after placement of a microcatheter into the MCA clot and infusion of 120,000 U of urokinase. There is no recanalization. **C**, Angiogram after infusion of 1 million U of urokinase directly into the clot, showing complete recanalization of the MCA.

recanalization of an occluded vessel. When infusion of thrombolytic agents often requires 1 to 2 hours for complete thrombus dissolution, time to recanalization can be quite long. Mechanical devices offer the possibility of considerably shortening time to recanalization. Devices may be able to clear thrombi from large arteries within a few minutes. The use of thrombolytic agents may not be necessary, possibly reducing the rate of intracranial hemorrhage.

The revolutionary Merci Retriever clot retrieval device (Concentric Medical Inc., Mountain View, CA, USA) received FDA approval for the removal of blood clots from the brain in patients experiencing ischemic stroke after it was shown to be effective in restoring vascular patency in patients within 8 hours of symptom onset and could serve as an alternative therapy for patients who are otherwise ineligible for thrombolytic drug administration.⁷² The Merci device is a flexible nickel titanium (i.e., nitinol) wire that assumes a helical shape once it is passed through the tip of the guidance catheter. In practice, the catheter/wire is passed distal to the thrombus, the catheter is removed, and a helical configuration is assumed by the wire. The clot is then trapped in the helix and withdrawn from the vasculature. Second-generation Merci devices (e.g., L5 Retriever) have been developed and their use shown to be associated with higher rates of recanalization, although these differences did not achieve statistical significance. They also produced lower mortality and a higher proportion of good clinical outcomes.⁷³ Mechanical embolectomy using an aspiration platform was the basis for the creation of the Penumbra System (Penumbra Inc., Alameda, CA, USA), which uses a microcatheter and separator-based debulking approach that allows for continuous aspiration of thrombus. A recent trial found that the Penumbra System resulted in safe and effective revascularization in patients who present with large vessel occlusive disease within 8 hours of stroke onset, as 81.6% of patients achieved a Thrombolysis In Myocardial Infarction (TIMI) grade of 2 or 3.⁷⁴

First-Generation Randomized Trials of Intraarterial Therapy

Three clinical trials investigated the role of intraarterial therapy as an alternative or adjunctive treatment to standard medical therapy. The SYNTHESIS trial compared IV thrombolysis alone to intraarterial therapy alone and showed comparable outcomes in both cohorts despite an hour delay in initiating IA therapy.⁷⁵ While the trial did not observe improved outcomes in the IA therapy group, it did not require documentation of a large vessel occlusion before initiation of treatment; 92 patients were treated with IA therapy outside the context of

the trial, further diluting the study population of patients likely to benefit from IA therapy. The MR RESCUE trial implemented a penumbra imaging-based paradigm in which patients were randomized to medical versus intraarterial therapy.⁷⁶ There was no difference between groups. Finally, IMS 3 compared the additional benefit of mechanical thrombectomy in patients receiving IV tpa.⁷⁷ Once again, IA therapy proved to be safe but no more efficacious than medical therapy. However, it is likely that a high percentage of patients had little or no chance of benefit.⁷⁸ Time to treatment was prolonged, as the mean IV tpa start to groin puncture time was 81 ± 27 minutes and the mean groin to IA start time was 41 ± 21 minutes, with a greater than 2-hour delay between CT head and groin puncture.⁷⁹

Stent Retrievers and Recent Trials

These three first-generation trials highlighted an important concept in revascularization—namely, that treatment likely favors patients with a large clinical deficit in the setting of a small core on presentation who undergo early and effective recanalization. In 2012, the FDA approved two new devices for the indication of thrombus removal in acute stroke, SOLITAIRE and TREVO. Both devices are in the stent retriever class of mechanism and consist of intracranial stents that can be delivered across thrombus with the dual benefit of achieving a temporary endovascular bypass and trapping the clot within the struts of the stent. The stent retriever is subsequently recovered along with the thrombus. In comparison to the MERCI device, stent retrievers yield higher rates of high-quality recanalization (86%–89% vs. 60%–66%).^{80,81} Several randomized clinical trials have now tested the hypothesis that IA therapy may be superior to medical management if revascularization is achieved implementing this new technology.^{82–86} The first trial to be completed was MR CLEAN, which demonstrated an adjusted common odds ratio of 1.67 in favor of intervention and an absolute difference of 13.5% in the rate of functional independence. These results prompted several ongoing trials to review their outcomes, and a similar benefit was seen across studies (see Tables 52-4 to 52-6).

Most of these trials focused on patients presenting within early time windows and the role of IA therapy at later time windows remains uncertain. Many practitioners favor revascularization for late time windows in basilar artery occlusive disease, given the high rate of mortality in this stroke subtype.⁸⁷ The role of IA therapy versus medical therapy in anterior circulation strokes presenting between 6 and 24 hours is currently being investigated.⁸⁸

Surgical Options

Cerebral edema and herniation are frequent causes of death from stroke in the first few days after massive infarction. Edema gradually increases and peaks 2 to 3 days after stroke onset. Steroids do not effectively reduce edema due to stroke, and antiedema measures such as mannitol or hyperventilation are of limited benefit. Control of intracranial pressure (ICP) is associated with improved outcome, but whether ICP monitoring is helpful to guide therapy remains unclear. Surgical decompression of large hemispheric infarcts causing edema and increased ICP is logical because the edema is usually self-limited.

If herniation can be avoided, recovery may occur similar to stroke without severe edema. Several different approaches to decompression have been proposed.

Hemicraniectomy is the first and most commonly performed procedure. It involves removal of a generous bone flap ipsilateral to the side of the infarction. Often, a durotomy is performed to allow outward herniation of the brain to decrease ICP and prevent downward herniation. For large MCA infarctions, timing of surgery, side of lesion, presence of signs of herniation prior to surgery, and involvement of other vascular territories do not significantly affect outcome.⁸⁹ This

analysis was obtained from uncontrolled, retrospective data; thus, no meta-analysis could be completed.

The optimal timing of hemicraniectomy in patients with malignant MCA infarction is unclear. If herniation is in progress, irreversible brainstem damage may occur, thereby limiting the benefit of the operation. More recent evidence suggests that surgical intervention should occur early regardless of whether signs of herniation are present. Three concurrent European trials (i.e., DECIMAL, DESTINY, HAMLET) including patients undergoing hemicraniectomy for malignant MCA infarction were combined in a pooled analysis.⁹⁰⁻⁹² In this analysis, thresholds were established for 45 hours to randomization and 48 hours to surgery from stroke onset. The combined results showed that decompressive surgery undertaken within 48 hours of stroke onset decreased mortality and increased the number of patients with a favorable functional outcome.⁹³

Surgical decompression for hemispheric infarction should be considered for younger patients with a greater potential for recovery from massive stroke. The role of surgical decompression of extensive MCA stroke in patients greater than 60 years of age remains controversial. A comparison of medical management versus early decompression in patients greater than 60 years of age in the DESTINY 2 trial did show improved survival in the surgical group, although a majority of the survivors required assistance for most daily activities. Cerebellar infarction is a special case that requires urgent surgical intervention.⁹⁴ Compression of the brainstem and fourth ventricle leading to hydrocephalus or severe pontomedullary compromise can be reversed by rapid surgical decompression of the infarcted cerebellum.

Other Medical Therapies

Anticoagulation

The use of anticoagulants in acute stroke is controversial, although several randomized clinical trials provide information regarding its efficacy. Retrospective data previously suggested a significant incidence of early recurrences after ischemic stroke, with reported rates of 20%. These studies also suggested that anticoagulation with heparin reduced recurrences. Hemorrhagic complications were acceptably low, particularly when patients with large strokes and uncontrolled hypertension were excluded from treatment. The results of recent randomized clinical trials have challenged these findings and call into question the value of anticoagulation for treatment of acute stroke.⁹⁵ However, more recent studies indicate that for cardioembolic stroke, warfarin can be safely started shortly after stroke without bridging therapy with heparin or enoxaparin.⁹⁶

The studies do not support a reduced recurrence rate or improved outcome with anticoagulation when given within 24 to 48 hours of stroke onset. Hemorrhage rates ranged from 1% to 2.5%. The results suggest that there is little value in anticoagulation for all patients with acute stroke, but it remains possible that some subgroups benefit. The TOAST study suggested that patients with large vessel disease may achieve better functional outcome with anticoagulation.⁹⁷ The relatively high hemorrhage rate in some studies also may have obscured some benefit. In the International Stroke Trial (IST), a significant reduction in recurrent strokes from 3.8% in the control group to 2.9% in patients treated with subcutaneous heparin ($P < 0.01$) was offset by an increase in hemorrhagic stroke from 0.4% in controls to 1.2% in patients receiving heparin ($P < 0.00001$).⁹⁸ Even in patients with atrial fibrillation, the value of early anticoagulation is uncertain, with some studies showing benefit and others showing lack of benefit in reducing recurrent stroke.⁹⁵ If anticoagulation is started, it should only be given more than 24 hours after intravenous thrombolysis and after imaging confirmation that no hemorrhagic transformation has occurred. The roles of newer anticoagulant drugs such as rivaroxaban, apixaban, and dabigatran in the acute stroke setting remain unclear, although, similar to warfarin, acute administration of these medications is likely safe if the stroke burden is small. These medications have the added benefit of not requiring bridging therapy, as therapeutic dosage is reached early after administration.

Antiplatelet Therapy

There is less uncertainty about the benefit of aspirin in acute stroke. Two large, randomized controlled trials, CAST⁹⁹ and IST,⁹⁸ showed a small but significant improvement in outcome in patients treated with aspirin. In IST, patients received 300 mg of aspirin daily for 14 days. There was a significant reduction in stroke recurrence within 14 days in the aspirin group (2.8%) versus nonaspirin groups (3.9%) and a significant decrease in the risk of death or nonfatal recurrent stroke in the aspirin group (11.3%) versus nonaspirin group (12.4%). In CAST, 160 mg of aspirin was given per day for 4 weeks or until hospital discharge. In the aspirin group, there was a significant reduction in death within 4 weeks (3.3%) versus placebo (3.9%) and a significant reduction in death or nonfatal stroke during hospitalization. There also was a significant reduction in recurrent ischemic strokes in the aspirin group (1.6%) versus placebo (2.1%), which was offset only by a trend of excess hemorrhagic strokes (aspirin 1.1% versus placebo 0.9%).

CAST and IST were designed to be considered together and include more than 40,000 patients. Combining the results of both studies shows a significant reduction in recurrent stroke of 7 per 1000 ($P < 0.000001$) and reduction of death or dependency of 12 per 1000 ($P = 0.01$).¹⁰⁰ The risk of aspirin in the absence of thrombolytics is minimal, and the small but significant benefit argues in favor of routine treatment, but only after 24 hours if intravenous thrombolysis has been used and absence of hemorrhagic transformation is confirmed.

The initiation of dual antiplatelets (aspirin and clopidogrel) was shown to reduce recurrent ischemic events in patients with TIA or mild strokes in the CHANCE trial. The generalizability of this study across populations is unclear, as the trial was conducted in China where there is a higher incidence of intracranial atherosclerotic disease (compared to the U.S. population) and so the treatment effect may reflect a particular benefit of dual antiplatelets in this stroke subtype. Furthermore, the metabolism of the prodrug clopidogrel into the active form is dependent on several P450 enzymes, with highly variable degrees of active drug across individuals depending on particular genetic variants of the enzyme. A study design similar to CHANCE is being pursued in the ongoing POINT trial in the U.S. population.

Statin Therapy

Statins reduce the incidence of strokes among patients who are at increased risk for cardiovascular disease. However, whether statins reduce the risk of stroke after a recent stroke or TIA was established by the SPARCL trial. In SPARCL, patients who had a stroke or TIA within 1 to 6 months before randomization, had LDL of 100 to 190, and had no known coronary artery disease were randomized to receive 80 mg of atorvastatin or placebo. The primary end point was a first nonfatal or fatal stroke. In the cohort receiving high-dose atorvastatin, the overall incidence of strokes and cardiovascular events was reduced. High-dose atorvastatin should thus be administered in the setting of acute ischemic stroke.¹⁰¹

Special ICU Management Considerations

General Assessment

In patients with acute stroke, initial concerns include assessment of respiratory function, cardiovascular stability, and level of consciousness. An adequate airway must be established to ensure proper ventilation, particularly in obtunded or comatose patients. Aspiration is a serious concern that often results in pneumonia and serves as a major cause of morbidity and mortality during hospitalization. Supplemental oxygen is often administered, but the benefit is uncertain when oxygenation is already adequate. Hypoxemia should be corrected immediately, however, and its source aggressively investigated. Arrhythmias are common in acute stroke, as bradycardia may signal underlying increased ICP or cardiac ischemia. Atrial fibrillation associated with rapid ventricular response often impairs cardiac output requiring immediate treatment and may also be an embolic source of stroke. Ventricular tachycardia or fibrillation rarely occurs with stroke; when

present, it usually is the result of coexistent myocardial infarction. Hypotension should be corrected with intravenous fluids. Seizures should be controlled with anticonvulsants. Fever should be treated aggressively with antipyretics.

Blood Pressure

Hypertension often accompanies ischemic stroke, and in most cases abrupt lowering of blood pressure is not advised because of the risk of further impairing perfusion in the ischemic region.¹⁰² In the presence of a systemic or cardiac reason for reducing blood pressure, such as aortic dissection or acute myocardial infarction, the relative importance of the systemic and neurologic issues must be considered. Hypertensive encephalopathy is a syndrome of extreme hypertension, papilledema, altered mental status, microangiopathic hemolytic anemia, and renal insufficiency that responds to the lowering of blood pressure. In the absence of papilledema or systemic features, it is unlikely that acute neurologic deficits are caused by hypertensive encephalopathy, and acute lowering of blood pressure will more likely worsen than improve deficits.

When thrombolytic therapy is considered, reducing blood pressure within the prescribed limits is necessary. Before thrombolytic therapy is given, systolic blood pressure should be less than 185 mm Hg and diastolic less than 110 mm Hg.¹⁷ Labetalol typically is administered in increasing doses every 5 to 10 minutes to control blood pressure. Enalapril is a reasonable alternative. Sublingual nifedipine should be avoided because of its potential to lower blood pressure precipitously. If these agents do not provide adequate control, a nicardipine drip could be considered, although such patients may not be good candidates for thrombolysis. Following thrombolysis, blood pressure should be aggressively controlled, keeping systolic blood pressure below 185 mm Hg and diastolic pressures below 110 mm Hg for the first 24 hours.

Fluids

Most patients with acute stroke are volume-depleted, and intravenous fluids should be replete with either normal saline or lactated Ringer's solution. In patients with large strokes in danger of developing brain edema, fluid administration should be titrated carefully, and free water should be limited. Mild hyponatremia need not be treated acutely, but more severe hyponatremia should be corrected slowly and usually reverses with infusion of normal saline.

The role of hypertonic saline (3-23%) in the treatment of acute ischemic stroke and its ability to minimize cerebral edema remains controversial. Those who oppose its use cite that it can lead to rebound parenchymal swelling once it is weaned off. Proponents will usually use a goal serum sodium range of 145 to 150 mEq/L and a serum osmolality goal of 315 to 320 mOsm/L. Sodium and serum osmolality levels are usually checked every 6 hours.^{103,104}

Glucose

Evidence from animal models of stroke suggests that hyperglycemia increases the severity of ischemic injury.¹⁰⁵ Increased glucose concentration in the area of ischemia causes higher lactate concentrations and local acidosis, which increases free radical formation and thus damages neurons. Hyperglycemia also may increase ischemic edema, release excitatory amino acid neurotransmitters, and weaken blood vessels in the ischemic area. Studies of stroke in humans show an inconsistent association between outcome and initial blood glucose; however, admission glucose concentration correlates with initial stroke severity. Initial hyperglycemia also has been associated with higher mortality rates after stroke.¹⁰⁶ Some suggest that hyperglycemia in acute stroke is a stress reaction, but the relationship between initial blood glucose concentration and outcome is independent of initial stroke severity, arguing against a stress phenomenon.

The GIST-UK trial investigated whether treatment with a glucose-potassium-insulin (GKI) infusion to maintain euglycemia immediately after the acute stroke event had an impact on mortality at 90 days. This trial was stopped due to slow enrollment but concluded that whereas

GKI infusions reduced plasma glucose concentrations and blood pressure, treatment was not associated with clinical benefit. The study was underpowered, and alternative results should not be dismissed.¹⁰⁷ The GRASP pilot trial found that insulin infusion for patients with acute ischemic stroke is feasible and safe. Three treatment arms were used, employing controls that were tight (70-110 mg/dL), loose (70-200 mg/dL), and usual (70-300 mg/dL).¹⁰⁸ Additional comparative studies should help to clarify future treatment regimens.

SUMMARY

The availability of effective treatment to alter outcome within the first few hours after stroke onset is rapidly evolving. Patients with symp-

KEY POINTS

1. When an arterial occlusion occurs, an area of irreversibly infarcted brain (core infarct) is surrounded by a region of reduced blood flow impairing function (ischemic penumbra) that is not yet severe enough to result in irreversible infarction. If adequate blood flow can be restored within a critical time frame, this area of at-risk tissue may be salvageable and return to normal function.
2. Acute ischemic stroke imaging ideally involves some combination of a noncontrast head CT, CT angiography of the head and neck, CT brain perfusion, MRI brain, MRA of the head and neck, or MR brain perfusion.
3. The only FDA-approved therapy for acute ischemic stroke presenting within 3 hours of symptom onset is intravenous t-PA.
4. Evidence from the ECASS III trial indicates that the therapeutic window for intravenous t-PA may be extended to 4.5 hours in select patients.
5. Several studies (MR CLEAN, EXTEND-IA, ESCAPE, SWIFT PRIME, and REVASCAT) have demonstrated improved outcomes in select patients undergoing intraarterial therapy with a stent-retriever device within 6 to 12 hours of symptom onset.
6. Intraarterial therapy for acute ischemic stroke presenting beyond 6 hours is currently under investigation in the DAWN study.
7. Surgical decompression for large infarctions is recommended to be completed within 48 hours from symptom onset in appropriately selected patients.
8. In patients receiving intravenous thrombolysis, no anticoagulation or antiplatelet agents should be administered in the first 24 hours until hemorrhagic transformation can be excluded. After that time, anticoagulation can be started in appropriate patients. If anticoagulation is not used, antiplatelet agents should always be started.
9. High-dose statin therapy can be administered acutely after ischemic stroke in patients with previous stroke or TIA and without history of coronary artery disease.
10. Patients presenting with TIA or mild stroke may be at high risk for recurrent events. A short course of dual antiplatelets may play a role in reducing the likelihood of recurrent ischemic events in patients.
11. Hyperglycemia needs to be treated aggressively, as it has been associated with higher mortality in acute ischemic stroke patients.

toms suggesting cerebral ischemia must be treated emergently, and imaging must be performed rapidly and in a high-quality manner. Therapy for acute stroke includes much more than thrombolysis, and understanding the benefits and hazards of thrombolysis continues to evolve with greater experience and additional clinical trials. Newer generations of mechanical devices are being developed, and neuroprotection and neurorestoration hold great promise as synergistic complements to stroke reperfusion therapies. Appropriate management of blood pressure, glucose, and intravenous fluids all

contribute to the overall outcome from acute stroke. At present, only a small fraction of patients with stroke (less than 5%) arrive at an emergency department in time for acute stroke therapy. Development of new acute stroke therapies and expected improvements in outcome with lower hemorrhage rates should encourage the medical system to further support the framework for a seamless and integrated stroke system of care. Such efforts should ensure that all stroke patients receive the optimal available therapy in the shortest time possible.

- This landmark study was the first randomized controlled trial to compare the efficacy of first-generation intraarterial therapy as an adjunctive therapy to intravenous thrombolysis compared to intravenous thrombolysis alone. While the results were neutral in the two study groups, analysis of this trial identified a potential benefit with adjunctive intraarterial therapy in patients with small infarct on presentation with documented proximal large vessel occlusion undergoing fast and high quality recanalization.*
- Chen ZM, Sandercock P, Pan HC, et al. Indications for early aspirin use in acute ischemic stroke: a combined analysis of 40,000 randomized patients from the Chinese Acute Stroke Trial and the International Stroke Trial. On behalf of the CAST and IST collaborative groups. *Stroke* 2000;31: 1240-49.
- This article represents a combined analysis of two clinical trials, each with 20,000 patients, showing a reduction in recurrent stroke and death rates with aspirin treatment. There was a highly significant reduction of 7 per 1000 in recurrent ischemic stroke in patients treated with aspirin versus control and a significant reduction in death rate of 4 per 1000 with aspirin treatment. Thus, early aspirin treatment is of benefit for a wide range of patients, and its prompt use should be widely considered for all patients with suspected acute ischemic stroke to reduce the risk of early occurrence.*

- This is the first randomized controlled trial confirming the efficacy and safety of alteplase given between 3 and 4.5 hours after the onset of a stroke. There are some exclusion criteria in addition to the normal contraindications for administration of intravenous t-PA for this extended therapeutic window. Intravenous alteplase administered between 3 and 4.5 hours significantly improved clinical outcomes in patients with acute ischemic stroke, but it was also more frequently associated with symptomatic intracranial hemorrhage versus placebo.*
- The ATLANTIS, ECASS and NINDS rt-PA Study Group Investigators. Association of outcome with early stroke treatment: pooled analysis of ATLANTIS, ECASS and NINDS rt-PA stroke trials. *Lancet* 2004;363:768-74.
- This article represents a combined analysis of five clinical studies in 2775 patients randomly allocated to rt-PA or placebo. The study addresses the use of intravenous rt-PA and provides specific insight into its use beyond 3 hours of the onset of stroke. The authors concluded that the sooner that rt-PA is given to stroke patients, the greater the benefit, especially if started within 90 minutes. Their findings also suggested a potential benefit from this therapy applied beyond 3 hours, but this potential might come with some risks.*
- The National Institute of Neurological Disorders and Stroke rt-PA Stroke Study Group. Tissue plasminogen activator for acute ischemic stroke. *N Engl J Med* 1995;333:1581-87.
- A key clinical report in the field of stroke that showed, for the first time in a randomized controlled trial, a reduction in stroke morbidity with acute treatment. In June 1996, the FDA approved intravenous t-PA for the treatment of stroke within 3 hours of onset.*

INTRACEREBRAL HEMORRHAGE

Spontaneous (nontraumatic) intracerebral hemorrhage (ICH) accounts for approximately 10% of all strokes in North America and about 20% to 30% in East Asia. Outcomes are typically poor; up to half die within 30 days, and survivors often have significant disability.¹

Pathophysiology

The mechanisms that account for brain injury from ICH are complex. The primary damage is local tissue destruction as rupture of a vessel introduces a sudden stream of blood into the brain parenchyma. In many, further bleeding results in hematoma enlargement within the first few hours of onset.² The mass of the hematoma produces tissue distortion and shifts within the intracranial cavity.

Further damage is believed to occur after the bleeding stops. Proposed causes include ischemia, edema, and toxic effects of parenchymal blood. While each of these can be detected in animal models, their clinical importance remains unsettled.

Despite experimental models of ICH^{3,4} and studies in human patients⁵⁻⁷ consistently demonstrating reduced blood flow around the hematoma, this does not appear to represent ischemia.^{8,9} Positron emission tomography (PET) and magnetic resonance imaging (MRI) studies in humans indicate that the perihematomal cerebral metabolism is reduced to a greater degree than the cerebral blood flow (CBF) and that biopsies from ICH patients demonstrate impaired mitochondrial function.¹⁰ These findings suggest that hypoperfusion reflects reduced metabolic demand of the tissue surrounding the hematoma rather than ischemia.^{9,11}

Cerebral edema occurs within hours of experimental ICH and may result from the toxic effects of blood-derived enzymes, increased osmotic pressure exerted by clot-derived serum proteins, or ischemia.¹² The cause, time course, and importance of edema formation in humans are debated, and the best predictor of the edema volume is the size of the hematoma. Early edema does not appear to contribute to increases in mass effect,¹³ worsened functional outcome, or increased mortality.¹⁴

Causes and Risk Factors

The leading risk factor for ICH, present in over half of all cases, is chronic hypertension.¹⁵ There is a doubling of the rate of hemorrhage with each decade of life until 80 years of age.¹⁶ The impact of smoking,¹⁷ alcohol abuse,^{18,19} and diabetes mellitus^{20,21} on the risk of ICH is disputed.

Hypertensive Hemorrhage

Hypertensive ICH predominantly occurs deep in the cerebral hemispheres, most often in the putamen,²² thalamus, lobar white matter, cerebellum, and pons (Fig. 53-1). The link between these sites is that they are all supplied by small penetrating arteries²³—that is, perpendicular branches directly off major arteries that are subject to high shear stress and that have no collaterals.

Intracranial Aneurysms and Vascular Malformations

Although aneurysmal rupture is most commonly associated with hemorrhage in the subarachnoid space, the blood may also be directed into the substance of the brain. Aneurysms located at the middle cerebral artery bifurcation can produce hemorrhages into the basal ganglia similar to hypertensive hemorrhage, and anterior communicating artery aneurysms can produce flame-shaped hemorrhages at the base of the frontal lobes.

About half of adults with intracranial arteriovenous malformations (AVMs) present with hemorrhage.²⁴ In 60% of cases, the hemorrhage is parenchymal, involving virtually any location of the brain.²⁵ Hemorrhage due to AVM occurs more frequently in a younger population than that due to aneurysms or hypertension.

Other Causes

Cerebral amyloid angiopathy (CAA) is an important cause of predominantly lobar, often recurrent, ICH in the elderly. The prevalence of amyloid deposition in cerebral vessels increases dramatically with age^{26,27} and may contribute to the exponential rise in the risk of ICH with increasing age. Apolipoprotein E $\epsilon 2$ and $\epsilon 4$ genotypes are associated with an earlier age at onset of first hemorrhage and a higher risk of early recurrence.^{28,29} The presence of multiple or recurrent lobar ICH (including asymptomatic microhemorrhages detected on gradient-echo MRI) in individuals 55 years or older without other known causes of hemorrhage strongly suggests this etiology.³⁰

Hematologic causes of ICH include antithrombotic and thrombolytic agents, systemic disease (e.g., thrombocytopenia, leukemia, and hepatic and renal failure), and congenital or acquired clotting factor deficiencies. The incidence of oral anticoagulant-associated ICH has been increasing in parallel with the rising use of the anticoagulant warfarin. Although the risk of ICH is greater with a supratherapeutic international normalized ratio (INR), a significant number of hemorrhages occur when the INR is therapeutic.³¹ Hematoma expansion among warfarin users may be more common and occur over a longer time frame, contributing to a higher mortality rate versus spontaneous ICH.³² Recently, a new class of oral anticoagulants has been introduced, which act by inhibition of thrombin or factor Xa and may have a lower risk of ICH than warfarin.³³⁻³⁶

Most studies suggest that antiplatelet use at ICH onset is not associated with larger hematoma size, hematoma growth, or poor clinical outcome.³⁷ Platelet dysfunction is associated with hematoma expansion and worse outcome,³⁸ but, to date, platelet transfusion has not provided a mortality benefit or improved functional outcome.³⁹

Hemorrhage from an underlying neoplasm is rare but occasionally occurs with malignant primary CNS tumors such as glioblastoma multiforme and lymphoma as well as with metastatic tumors.⁴⁰

ICH may also occur in association with infection (e.g., infiltration of vessel wall by fungal organisms,⁴¹ necrotizing hemorrhagic encephalitis with herpes simplex⁴²), vasculitis,⁴³ venous sinus occlusion,⁴⁴ in a delayed fashion after head trauma,⁴⁵ following reperfusion (e.g., after carotid endarterectomy or acute thrombolysis),⁴⁶ and with the use of various drugs, particularly sympathomimetics (e.g.,

FIGURE 53-1 ■ Typical moderate-sized putaminal hemorrhage.

cocaine, amphetamines, pseudoephedrine, and phenylpropanolamine).⁴⁷ Finally, some degree of hemorrhagic transformation of acute cerebral infarcts is common,⁴⁸ although symptomatic ICH in this setting is rare in the absence of anticoagulation or thrombolytic therapy.

Clinical Features

The clinical presentation of ICH is often indistinguishable from that of ischemic stroke; however, ICH more commonly presents with an altered level of consciousness, headache, and vomiting.²² Blood pressure is elevated in the majority of patients (see below). Clinical as well as purely electrographic seizures may occur at onset or in the first few days, particularly in those with lobar hemorrhages or underlying vascular or neoplastic lesions.⁴⁹ Symptoms may be maximal at onset or evolve over minutes to hours. Neurologic deterioration within 48 hours after hospital admission has been reported to occur in 20% of patients.⁵⁰ A majority are related to hematoma expansion, but for some, the cause is not always evident.

Diagnostic Studies

Noncontrast computed tomography (CT) scanning is the gold standard for the diagnosis of acute ICH. The typical CT appearance of an acute hematoma consists of a well-defined area of increased density surrounded by a rim of decreased density. Over time, the borders of both the high- and low-attenuation regions become increasingly indistinct such that the hematoma is isodense with adjacent brain parenchyma by 2 to 6 weeks.⁵¹ Although MRI also has high sensitivity and specificity for the diagnosis of acute ICH,⁵²⁻⁵⁴ it is less accessible in the emergency department setting, and its use has safety concerns in patients with impaired consciousness, with hemodynamic compromise, or who are vomiting.⁵⁵ The benefits of MRI over CT are its greater accuracy in determining the approximate age of a hematoma⁵⁶ and its ability to detect evidence of previous asymptomatic hemorrhages.⁵⁷

Angiography is useful in evaluating the cause of ICH if an underlying aneurysm or vascular malformation is suspected, but the yield is extremely low when the patient has chronic hypertension and the hemorrhage is in one of the typical sites associated with hypertensive hemorrhage.⁵⁸ Multidetector CT angiography is an alternative imaging modality and has a sensitivity of 96% and a specificity of 99% to 100%.^{59,60} The yield is higher in younger patients (47%), those without hypertension or impaired coagulation, and those with lobar (20%) or infratentorial (16%) ICH locations.⁵⁹

Multidetector CT angiography can also be used to identify the presence of active contrast extravasation into the hematoma, an indicator of active hemorrhage. Termed the *spot sign*, these foci of intralesional enhancement are seen in up to one-third of patients with acute ICH⁶¹ and are associated with an increased risk of hematoma expansion, in-hospital mortality, and poor outcome in survivors.⁶²

Treatment

Initial Stabilization

Acute ICH is a medical emergency requiring careful attention to the airway, blood pressure, and correction of any underlying coagulopathy. As many as half of all patients with ICH require mechanical ventilation.⁶³ Blood pressure is often elevated at presentation, sometimes markedly so, and early control is an important component of initial stabilization. Finally, urgent identification and correction of coagulopathies are important.

Airway and Respiratory Management

With diminished consciousness, the pharyngeal and tongue musculature relax, and cough and gag reflexes are inhibited, leading to airway compromise. Additionally, if the hemorrhage is in the brainstem or cerebellum, there may be complete loss of pharyngeal tone and early airway obstruction.

Initial airway management includes proper positioning, frequent suctioning, and placement of an oral or nasal airway. If sonorous respiration, inability to manage oral secretions, or decreased oxygen saturation does not improve, intubation is necessary. Premedication should be administered to produce adequate sedation and jaw relaxation as well as to prevent elevation of intracranial pressure (ICP) due to hypoxia, hypercarbia, and direct tracheal stimulation. Short-acting intravenous (IV) anesthetic agents (thiopental 1 to 5 mg/kg, or etomidate 0.1 to 0.5 mg/kg) block this response⁶⁴ and additionally suppress brain metabolic rate,⁶⁵ theoretically improving tolerance of a transient fall in cerebral perfusion pressure (CPP) should it occur. Etomidate is generally preferred over thiopental since it is less likely to lower blood pressure. IV lidocaine (1 to 1.5 mg/kg) has been recommended to block this response,⁶⁶ although data supporting its use are lacking.⁶⁷ Paralytic agents are usually unnecessary, but, if needed, short-acting agents should be used.

Hemodynamics

Arterial blood pressure is elevated on admission in the majority of patients with ICH, even in the absence of a history of hypertension.^{22,68} Although this acute increase in blood pressure is often implicated as the cause of the hemorrhage, it more likely reflects chronic hypertension, the brain's attempt to maintain CPP in response to the sudden increase in ICP, pain, anxiety, and sympathetic activation. Even without treatment, blood pressure tends to decline to premonitory levels within a week of ICH.⁶⁹

There has been substantial controversy over if and when to lower elevated blood pressure after acute ICH.⁷⁰ Proponents of rapid treatment of acute hypertension argue that high blood pressure may predispose to hematoma enlargement and exacerbate vasogenic edema by increasing capillary hydrostatic pressure, especially in areas with a damaged blood-brain barrier. Another compelling reason to lower blood pressure in ICH patients with moderate to severe hypertension is the potential for end organ damage including myocardial ischemia, congestive heart failure, and acute renal failure.

The major argument against the treatment of elevated blood pressure has been that lowering blood pressure might reduce CBF and exacerbate ischemia surrounding the hematoma.⁷¹ Since chronic hypertension shifts the cerebral autoregulatory curve to the right, a higher CPP may be required to maintain adequate CBF.^{72,73} Lowering the blood pressure to "normal" levels might thus lead to ischemic damage. Similarly, lowering blood pressure may critically reduce CPP in patients in whom ICP is elevated due to a large space-occupying clot or hydrocephalus.

Several studies have addressed this issue in patients with mean arterial pressure (MAP) more than 130 to 140 mm Hg.⁷⁴⁻⁷⁶ These studies demonstrate that regional and global CBF are preserved when MAP is lowered to 110 mm Hg or about 80% of the admission MAP.

These observations set the stage for the INTERACT trial,⁷⁷ a prospective trial of blood pressure management beginning within 6 hours of symptom onset in 404 patients with spontaneous ICH and elevated systolic blood pressure (SBP, 150 to 220 mm Hg). Patients were randomized to an early, intensive blood pressure-lowering group (goal SBP <140 mm Hg within 1 hour), or a control group (goal SBP <180 mm Hg). After adjusting for initial hematoma volume and time from onset to CT, median hematoma growth at 24 hours differed by 1.7 mL (95% CI, 0.5-3.9, $P = 0.13$). Intensive blood pressure-lowering did not increase the risk of adverse events or improve 90-day clinical outcome. This was followed by the much larger INTERACT2, which used the identical protocol and enrolled almost 3000 patients.⁷⁸ Again there was a very small, if any, impact on hematoma expansion, although the hematoma sizes of those enrolled were fairly small (median, 11 mL). Although the study did not reach its primary endpoint, an ordinal analysis of modified Rankin scores indicated improved functional outcomes with intensive lowering of blood pressure. Based on this study, many clinicians are now more aggressive in treating early hypertension in these patients.

In the setting of ICH, the ideal antihypertensive agent would be easily titrated, have minimal cerebrovascular effects, and not be prone to sudden, large reductions in blood pressure. Vasodilators, especially venodilators, can raise ICP by increasing cerebral blood volume and should be avoided. Sodium nitroprusside and nitroglycerin increase ICP and lower CBF in patients with reduced intracranial compliance and should not be used. Calcium channel blockers, beta-blockers, and angiotensin-converting enzyme inhibitors have minimal effect on CBF within the autoregulatory range of MAP and do not alter ICP. Therefore, popular treatment options in the setting of acute ICH include intermittent boluses of labetalol, enalapril, and/or hydralazine, or continuous infusion of nicardipine or clonidine.

Prevention of Hemorrhage Extension

Because hemorrhage extension occurs within the first few hours after symptom onset in about one-third of patients (Fig. 53-2), it seems reasonable to correct any existing coagulopathy as rapidly as possible.

Patients taking warfarin should receive IV vitamin K and replacement clotting factors. Until recently, fresh frozen plasma (FFP) was used for this purpose, but it can precipitate congestive heart failure and transfusion-related acute lung injury. Prothrombin complex concentrate (PCC) is an effective alternative that can be administered much more quickly without these risks.⁷⁹

Management of hemorrhage in patients taking thrombin and factor Xa inhibitors is more difficult. Animal models suggest that PCC may be effective as a nonspecific reversal agent. Although there are currently no FDA-approved antidotes, andexanet alfa (a recombinant factor Xa derivative) and idarucizumab (a humanized antibody fragment) are in phase III trials.

Symptomatic ICH occurs after thrombolytic treatment of acute ischemic stroke in about 6% of patients.⁸⁰ It is substantially less common after thrombolytic treatment of extracerebral thrombosis.⁸¹ No reliable data are available to guide correction of the thrombolytic effect of recombinant tissue plasminogen activator (rt-PA). Current practice is highly variable and may include administration of FFP, PCC, cryoprecipitate, and platelets.

Even in those patients without coagulopathy, promoting early hemostasis might limit ongoing bleeding and decrease hematoma volume. Factor VIIa is a coagulation factor that interacts with tissue factor exposed in the wall of a damaged blood vessel to drive a burst of thrombin that initiates platelet aggregation and accelerates formation of a stable fibrin clot. A phase IIb study found that treatment with recombinant factor VIIa (rFVIIa) given as a single IV bolus within 4 hours of ICH onset decreased hematoma growth and improved clinical outcome despite a small increase in thromboembolic events. A much larger phase III trial comparing placebo to 20 and 80 µg/kg of rFVIIa followed, which confirmed the ability of rFVIIa to reduce hematoma growth; however, at 90 days there was no significant difference in clinical outcome.⁸² A post hoc exploratory analysis suggested that a subgroup of younger patients who present earlier and have no significant intraventricular hemorrhage might benefit from rFVIIa, but this has not been tested to date.⁸³

Intraventricular Hemorrhage and Hydrocephalus

In about 40% of patients with ICH, blood extends into the ventricular system (intraventricular hemorrhage, IVH).⁸⁴ Mortality in these patients is high.^{85,86} Hydrocephalus may develop after ICH either in

FIGURE 53-2 ■ Example of hematoma enlargement. Computed tomography (CT) on left was obtained 2 hours after onset of left hemiparesis and shows right putaminal hemorrhage. CT on right was obtained 1 hour later when patient acutely deteriorated and shows expansion of hematoma, with intraventricular extension, midline shift, and enlarging ventricles.

FIGURE 53-3 ■ Example of a small thalamic hemorrhage with blood obstructing the foramen of Monro, causing hydrocephalus.

association with IVH or because of direct mass effect on a ventricle (e.g., on the third ventricle with a thalamic hemorrhage; Fig. 53-3). External ventricular drainage (ventriculostomy) is often used to treat hydrocephalus and IVH, but its efficacy has never been established. Ventriculostomy in the setting of IVH is difficult to manage because the catheter frequently becomes obstructed with thrombus, interrupting drainage and raising ICP. Flushing the system helps remove thrombus from the catheter but increases the risk of ventriculitis. Recently, investigators have attempted to facilitate removal of blood from the ventricles via direct intraventricular administration of thrombolytic agents. Preliminary studies have been promising,⁸⁷ and a multicenter randomized trial is currently under way.

Intracranial Hypertension

The incidence, impact, and appropriate management of intracranial hypertension in ICH are not well understood. Factors likely to elevate ICP include large hematoma size, minimal degree of underlying cerebral atrophy, hydrocephalus, and edema, but the true incidence of intracranial hypertension is unclear, since routine ICP monitoring is not performed. Because the hematoma is localized and the increase in volume it produces can be compensated for to some degree by reduction in the size of the ventricles and subarachnoid space, a global increase in ICP may not be seen unless the hemorrhage is very large or is associated with marked hydrocephalus. However, mass effect from the hematoma and local tissue shifts can compress the brainstem or result in herniation in the absence of a global increase in ICP.^{88,89} Thus, the utility of ICP monitoring is not clear. In some cases, external ventricular drain (EVD) placement is considered to manage hydrocephalus. Patient selection and timing are controversial; however, patients with small parenchymal hematomas who have deterioration in the level of consciousness and enlarging ventricles are most likely to benefit. Those with very large parenchymal hematomas are least likely to benefit, and placement of an EVD in the contralateral ventricle typically worsens tissue shifts, often leading to clinical deterioration.

Elevated ICP, edema, and tissue shifts are often treated with osmotic agents (mannitol, hypertonic saline) and, if the ventricles are enlarged, CSF drainage. More details on ICP management can be found in Chapter 56 of this book on head injury. There are only a few small clinical trials of osmotic agents in ICH, which do not provide sufficient data to support their routine use.⁹⁰ Furthermore,

corticosteroids in ICH do not provide benefit and increase the rate of complications.⁹¹

Surgical Evacuation

The rationale for surgical evacuation of a hematoma is that reducing mass effect and removing neurotoxic clot constituents should minimize injury to adjacent brain tissue and hence improve outcome. Early randomized controlled trials of surgery for supratentorial ICH in the mid to late twentieth century, however, failed to show a benefit.⁹²⁻⁹⁵ A meta-analysis of three of these trials reported that patients undergoing surgical evacuation via open craniotomy had a higher rate of death or dependency at 6 months compared to those managed medically (83% vs. 70%).⁹⁶ Criticisms of these trials are that outdated surgical techniques were used, patient selection was inadequate, and surgery was delayed. Because open craniotomy is complicated by tissue damage sustained during the approach to the hematoma, a variety of new techniques for clot removal have been proposed, including an Archimedes screw, ultrasonic aspirator, modified endoscope, modified nucleotome, double track aspirator, intraoperative CT monitoring, and instillation of thrombolytics. However, the recurrence of bleeding due to the loss of tamponade effect on adjacent tissue that occurs in 10% of patients treated with open craniotomy remains a concern. In addition, because the newer techniques involve limited surgical exposure, concern exists that rebleeding will be more difficult to control than with open craniotomy.

A lack of benefit of surgery in ICH was also shown in the STICH trial, a multicenter study in which 1033 patients were randomized within 72 hours of ICH onset to surgical hematoma evacuation (open craniotomy or stereotactic aspiration, at the surgeon's discretion) or initial conservative management. Outcome did not differ between groups. Subgroup analysis, however, suggested a possible benefit of surgery in patients with superficial hematomas (less than 1 cm from cortical surface).⁹⁷ This led to the STICH II trial, which enrolled conscious patients with superficial lobar ICH of 10 to 100 mL and no intraventricular hemorrhage, admitted within 48 hours of ictus. There was a trend toward better survival in the surgical group.⁹⁸ In a new phase III trial, patients are randomized within 48 hours of ictus to stereotactic placement of a catheter in the hematoma and instillation of rt-PA for up to 72 hours or medical management.⁹⁹

Due to the high risk of brainstem compression and hydrocephalus, cerebellar hemorrhages were excluded from the randomized trials of surgery. Case series report good outcomes for surgically treated patients with cerebellar hemorrhages that are large or associated with brainstem compression or obstruction of the fourth ventricle. Recommended criteria for when to evacuate a cerebellar hematoma have thus included diminished level of consciousness, large size of the hematoma (>3 cm³), midline location, compression of basal cisterns and/or brainstem, and presence of hydrocephalus (Fig. 53-4).¹⁰⁰⁻¹⁰² Patient selection is important as many patients with smaller hemorrhages do well with medical management.¹⁰³

Management of Seizures

Although seizures may theoretically exacerbate ICH, they have not been shown to alter outcome. Prophylactic anticonvulsants may reduce the risk of early seizures in patients with lobar ICH but do not affect the risk of developing epilepsy.¹⁰⁴ Thus, reasonable approaches include either a brief period of prophylaxis or treating only if seizures occur. As for any hospitalized patient, the treatment of clinical seizures typically begins with an IV benzodiazepine such as lorazepam followed by an IV agent such as fosphenytoin. Monitoring for and management of subclinical seizures is covered herein in Chapter 54.

Supportive Care

Patients with ICH are prone to the same medical complications seen in patients with ischemic stroke, including fever, deep venous thrombosis (DVT), pulmonary embolism, and pneumonia.^{105,106} Given the association between fever and worsened outcome in experimental models of brain injury, it is reasonable for antipyretic medications to

FIGURE 53-4 ■ Typical cerebellar hemorrhage with effacement of basal cisterns and early hydrocephalus manifest by enlargement of the temporal horns of the lateral ventricles.

be administered in febrile patients with ICH. The use of pneumatic sequential compression devices and elastic stockings significantly decreases the incidence of DVT in patients with acute ICH versus elastic stockings alone.¹⁰⁷ Subcutaneous heparin at a dose of 5000 units three times daily when initiated on day 2 after hemorrhage has been shown to significantly reduce the frequency of DVT relative to treatment begun on day 4 or 10, with no concomitant increase in hematoma expansion.¹⁰⁸ In another study, subcutaneous enoxaparin (40 mg daily) initiated at 48 hours after ICH was also safe. A benefit of enoxaparin over compression stockings could not be detected because of the low incidence of DVT in both treatment groups.¹⁰⁹

Similar to patients with ischemic stroke, ICH patients should not be fed orally until swallowing is evaluated. If aspiration is detected or the patient is not alert enough to eat safely, nasogastric tube feeding should commence promptly. Patients should be monitored for signs of aspiration pneumonia, whether taking food orally or via nasogastric tube.

Early mobilization and rehabilitation are generally recommended for clinically stable patients with ICH.

Prognostic Factors and Causes of Mortality

Mortality following ICH is high (25%-50%), with over half of the deaths occurring in the first 48 hours; the majority of ICH survivors have significant residual disability.^{1,110,111} The most consistent predictors of poor outcome are impaired level of consciousness and large hematoma size on admission. Other predictive features include age, hypertension, history of diabetes, antecedent warfarin use, male gender, in-hospital neurologic deterioration, hyperglycemia, elevated troponin level, elevated plasma S100B level, low serum cholesterol and triglyceride levels, and the presence of the apolipoprotein E ε2 or ε4 allele. Predictive radiographic features of poor prognosis include infratentorial hematoma location, intraventricular spread of blood, midline shift, hydrocephalus, hematoma growth, and the presence of the spot sign on CT angiography. A number of prognostic models have been developed to allow risk stratification upon presentation with ICH. One easy-to-use model is the ICH score,¹¹² which is based on point assignments for Glasgow Coma Scale score, ICH volume, presence of intraventricular hemorrhage, infratentorial location, and patient age and has been validated to accurately predict 30-day mortality.

Concern has been raised, however, that withdrawal of life-sustaining interventions in patients felt likely to have a poor outcome biases predictive models in ICH and negates the predictive value of other

FIGURE 53-5 ■ Autopsy specimen of intracranial aneurysm filled with pressurized blood to simulate subarachnoid hemorrhage.

variables.¹¹³ Thus, the most frequent cause of death after ICH is withdrawal of care, followed by early (within 48 hours) transtentorial herniation with progression to brain death. Medical complications of immobility (pulmonary embolism, pneumonia, sepsis) account for most of the subsequent deaths.¹¹¹

SUBARACHNOID HEMORRHAGE

Subarachnoid hemorrhage (SAH) usually is a sudden, dramatic event that has multisystem consequences. One-quarter of patients die before reaching medical attention,¹¹⁴ and because of secondary insults—rebleeding, hydrocephalus, and delayed ischemia—more than half of those who reach medical attention either die or are left with significant neurologic deficits.

Pathophysiology

In SAH, the primary site of bleeding is the subarachnoid space, but it may also involve hemorrhage into the brain parenchyma, ventricular system, or subdural space. Rupture of an intracranial saccular aneurysm (Fig. 53-5) is by far the most common cause of spontaneous SAH. Saccular, or berry, aneurysms are small, rounded protrusions of the arterial wall occurring predominantly at bifurcations of the large arteries of the circle of Willis at the base of the brain. The most common sites of ruptured aneurysms are the distal internal carotid artery and its posterior communicating artery junction (41%), anterior communicating artery/anterior cerebral artery (34%), middle cerebral artery (20%), and vertebrobasilar arteries (4%).¹¹⁵ About 20% of patients have multiple aneurysms.

Most aneurysms rupture at the dome, where the wall may be as thin as 0.3 mm. Tension on the aneurysm wall is determined by the radius of the aneurysm and the pressure gradient across the wall (law of Laplace). The probability of rupture is related to size; aneurysms less than 5 millimeters in diameter have a very low rate of rupture. Aneurysm rupture causes local tissue damage due to the jet of blood under arterial pressure, as well as a transient increase in ICP to match arterial pressure.

Causes and Risk Factors

Genetic conditions that predispose to aneurysm formation include polycystic kidney disease, connective tissue disorders, and coarctation

FIGURE 53-6 ■ Baseline angiogram obtained shortly after subarachnoid hemorrhage (*left*) and repeat angiogram obtained 7 days later (*right*) showing severe vasospasm of basilar artery, with reduced distal flow.

of the aorta. Recently, it has become clear that in some patient populations, genetic factors play a role in aneurysm formation without other associated conditions.¹¹⁶ There is a familial form as well.¹¹⁷ Other types of aneurysms that less commonly cause SAH include atherosclerotic, mycotic, and traumatic aneurysms. Trauma is the most common cause of nonaneurysmal SAH. Arteriovenous malformations, cocaine and stimulant abuse, neoplasia, and vasculitis account for the bulk of the remainder of cases. Bleeding into the subarachnoid space may accompany ICH, particularly in the setting of CAA. In 10% to 15% of cases of SAH, no source of bleeding is identified.

Clinical Features

Presentation

The most common initial symptom of SAH, occurring in over 90% of patients, is a sudden and severe (“thunderclap”) headache. Less severe warning (“sentinel”) headaches¹¹⁸ may precede the presenting event in as many as half of patients and are thought to represent minor aneurysmal leaks. In about half of patients, loss of consciousness accompanies the headache¹¹⁹ due to either the sudden surge in ICP at the moment of hemorrhage or cardiac arrhythmias. Vomiting can be a prominent symptom. Seizures may be reported,¹²⁰ but it is unclear whether this represents true epileptic seizures or reflex posturing related to the sudden rise in ICP. Focal deficits at the onset of hemorrhage occur in fewer than 10% of cases. After a few hours, a stiff neck can develop, reflecting the sterile meningeal inflammation induced by the presence of blood in the subarachnoid space.

Complications

A worsening of neurologic status often indicates one of the three major complications of SAH: rebleeding, hydrocephalus, or delayed cerebral ischemia (DCI). An understanding of the timing and nature of the deterioration facilitates rapid diagnosis and treatment. It must be emphasized that systemic perturbations such as infection, hyponatremia, fever, hypoxia, and hypotension may produce similar symptoms and should be sought and corrected as part of the evaluation process.

Early Complications. Rebleeding. Rebleeding is heralded by a sudden worsening of headache, vomiting, blood pressure elevation, development of a new neurologic deficit, or arrhythmia. It occurs in up to one-third of patients and is more often than not fatal. The risk of rebleeding is greatest during the first 24 hours (5%-10%), declining rapidly over the next 2 weeks.¹²¹ Rates of rebleeding are highest in women, those who are a poor clinical grade, those in poor medical condition, and those with elevated systolic blood pressure.

TABLE 53-1

Fisher Grade of Subarachnoid Hemorrhage on Initial Computed Tomography

1. No blood detected
2. Diffuse or vertical layers <1 mm thick
3. Localized subarachnoid clot and/or vertical layers ≥1 mm thick
4. Intraparenchymal or intraventricular clot with diffuse or no SAH

3. Thick cisternal clot without IVH
4. Thick cisternal clot with IVH

CT, computed tomography; IVH, intraventricular hemorrhage; SAH, subarachnoid hemorrhage.

Hydrocephalus. Hydrocephalus occurs after SAH because of disturbances of CSF flow or reabsorption: subarachnoid blood may impair CSF reabsorption at the arachnoid granulations, and ventricular blood may obstruct its flow. Acute hydrocephalus can develop within hours of SAH,¹²² often in the absence of intraventricular blood. It usually manifests as a gradual decline in the level of consciousness and can easily be treated by placement of an external ventricular drain. Delayed hydrocephalus may also develop gradually days to weeks later. If the acute hydrocephalus is untreated, about one-third of patients progress, one-third spontaneously improve, and one-third remain static.¹²³

Delayed Complications. Vasospasm. The term *vasospasm* refers to complex changes in intracerebral vessels, with segmental or diffuse narrowing of the lumen due to arterial wall thickening, vasoconstriction, and impaired relaxation that may reduce CBF. If the reduction in flow is severe enough, ischemia and infarction typically follow. The term *DCI* describes the clinical situation where these as well as other factors, including impaired autoregulation, hypovolemia, spreading cortical depression, and microthrombosis, combine to produce ischemia.¹²⁴ Arterial narrowing can be detected angiographically (Fig. 53-6) in up to 70% of patients,¹²⁵ of whom almost half will have symptoms. The onset of vasospasm is delayed, most commonly developing 5 to 10 days after initial hemorrhage, and may persist for up to 3 weeks. The strongest predictors of vasospasm are the clinical condition on presentation and the amount of subarachnoid blood on the initial CT scan. The highest risk is in those who have thick subarachnoid clots and intraventricular blood (graded using a modified Fisher Scale; Table 53-1).^{126,127} Focal neurologic deficits resulting from vasospasm may appear abruptly or gradually and may fluctuate,

FIGURE 53-7 ■ Electrocardiogram in a patient with acute subarachnoid hemorrhage, demonstrating diffuse T-wave inversions.

exacerbated by hypovolemia, hypotension, or fever. If untreated, infarction may occur.

Medical Complications. Blood pressure is often elevated after SAH and is associated with a greater risk of rebleeding, vasospasm, and higher mortality. Multiple factors may underlie the rise in blood pressure, including increased sympathetic outflow, agitation, and pain. Early on, blood pressure management focuses on treating hypertension to help prevent rerupture of the aneurysm. Following repair of the aneurysm, the risk of rebleeding is virtually eliminated, and spontaneous elevations in blood pressure should be allowed to occur without intervention, since the risk of vasospasm becomes the primary concern at this point in management.

Disturbances in sodium and water balance occur in about one-third of patients, and hyponatremia and volume depletion after SAH is correlated with an increased risk of symptomatic vasospasm and poor outcome.¹²⁸ Although hyponatremia was previously attributed to inappropriate secretion of antidiuretic hormone (SIADH) and was, therefore, treated with fluid restriction, later evidence suggested that both sodium and water are lost. In fact, when administered normal, “maintenance,” volumes of fluid (2 to 3 L/day), as many as half of patients develop intravascular volume contraction.¹²⁹

Cardiac abnormalities are common in the first 48 hours after SAH. Electrocardiographic (ECG) changes (Fig. 53-7), including tall peaked T waves (“cerebral T waves”), diffuse T-wave inversion, ST-segment depression, and prolonged QT segments,¹³⁰ occur frequently and are linked to elevated levels of circulating catecholamines. These changes usually do not represent myocardial ischemia, as the myocardial lesions reported are pathologically distinct from ischemia. Cardiac enzymes may be mildly elevated.¹³¹ Cardiac rhythm disturbances occur in about 30% to 40% of patients, especially on the day of hemorrhage or in the postoperative period, and arrhythmias are typically benign but can be life threatening in about 5%.^{132,133} In rare cases, a stunned myocardium, often referred to as Takotsubo’s cardiomyopathy, may occur, with impairment of myocardial contractility leading to a fall in cardiac output, hypotension, and pulmonary edema.¹³⁴ Apical ballooning is a common echocardiographic finding. This can be dramatic but is transient, usually lasting 2 to 3 days, after which cardiac function recovers.¹³⁵ Management is the same as with other causes of cardiogenic shock.¹³⁶ During hemodynamic treatment for vasospasm, pulmonary edema may occur in up to one-quarter of patients,¹³⁷ though its incidence is now lower with careful monitoring.¹³⁸

Diagnostic Studies

CT is the imaging modality of choice in screening for SAH, having a sensitivity of over 90%.¹³⁹ Blood appears as high attenuation within the basal cisterns, Sylvian fissure, and sulci (Fig. 53-8). CT may fail to demonstrate SAH if the volume of blood is very small, if the

FIGURE 53-8 ■ Computed tomography scan of acute subarachnoid hemorrhage, with a thick layer of hyperdense blood filling the basal cisterns.

hemorrhage occurred several days before the CT scan, or if the hematocrit is extremely low.¹⁴⁰ Lumbar puncture for CSF analysis is indicated if CT is negative and clinical suspicion is high. Red blood cells in the CSF are indicative of SAH but can also be seen with traumatic puncture. The common technique of comparing cell counts in the first and last tubes collected is not reliable; however, the presence of yellow pigment (xanthochromia), resulting from red cell breakdown, can help distinguish between the two.¹⁴¹ Xanthochromia develops 2 to 6 hours after hemorrhage and persists for 1 to 4 weeks. It can also be seen in the setting of high protein levels due to diabetes, renal failure, or infection, in which case spectrophotometric analysis to identify hemoglobin breakdown products improves diagnostic accuracy.¹⁴²

Once SAH has been diagnosed, cerebral angiography should be performed as soon as possible. Angiography fails to identify a source of bleeding in 10% to 15% of patients with nontraumatic SAH. Repeat angiography in about 1 week is thus recommended.¹⁴³ There is a subset of patients in whom the blood on CT is localized to the perimesencephalic cisterns. In these cases, angiography is usually negative, and the bleeding is thought to be venous in origin; the prognosis is typically excellent, and repeat angiography is almost always negative.¹⁴⁴

With its wide availability, ease of use, and safety profile, CT angiography is increasingly being used as the initial diagnostic tool in the investigation of SAH. Overall sensitivity is more than 90% compared to conventional catheter angiography but is notably lower for aneurysms smaller than 5 mm¹⁴⁵; thus, a negative CT angiogram should be followed by conventional catheter angiography except in the case of perimesencephalic SAH.¹⁴⁴ Magnetic resonance angiography (MRA) has good sensitivity for detecting medium and large aneurysms, but sensitivity falls to less than 40% for small aneurysms. In addition, MRA is impractical for many acutely ill patients with SAH. MRA and CT angiography may also be of assistance in planning surgical or endovascular approaches to treatment.

Treatment

In 2011, an international consensus conference on the critical care management of patients with SAH was held and evidence-based recommendations were developed.¹⁴⁶

Initial Stabilization

The initial steps in the evaluation of a patient with suspected SAH should include assessment of airway, hemodynamic status, and the

level of neurologic function. The Hunt and Hess Scale¹⁴⁷ and the World Federation of Neurological Surgeons Scale¹⁴⁸ provide standardized measures of the patient's clinical condition (Tables 53-2 and 53-3). These scales should be scored after the patient is stabilized, including treatment of hydrocephalus if indicated. If the patient is lethargic or agitated, elective intubation should be considered before angiography because sedation is often necessary for angiography and may result in unrecognized hypoventilation or airway obstruction during the procedure.

Routine Care and Monitoring

The routine monitoring of all patients with acute SAH should include serial neurologic examinations, continuous ECG monitoring, and frequent determinations of blood pressure, electrolytes, body weight, and fluid balance. Initial use of anticonvulsants is no longer routinely recommended for patients who have not had a seizure. Anticonvulsants may be given in the perioperative period for patients who undergo aneurysm clipping; however, the duration of administration should be limited to several days.¹⁴⁹ Recent retrospective studies have suggested that routine use of anticonvulsants for a longer duration is associated with worse neurologic outcome.¹⁵⁰ In the past, dexamethasone was widely used to reduce meningeal irritation and intra- and postoperative edema, but given the lack of supporting evidence, its use has fallen out of favor.

Fluid Management. A stable intravascular volume should be maintained by hydration with isotonic saline and daily monitoring of fluid balance, body weight, and hematocrit. Monitoring of fluid balance alone may not be adequate to prevent hypovolemia, and combining multiple clinical indicators of volume status is needed.^{151,152} In some patients with severe cerebral salt wasting, large volumes of fluid are required to prevent intravascular volume contraction.¹⁵³ Hyponatremia can often be managed with restriction of free water, by administering only isotonic IV fluids, minimizing oral liquids, and using concentrated enteral feedings. It is important to adjust the *tonicity* of the fluid rather than the *volume* of fluids administered. Fludrocortisone is of marginal benefit in treating salt wasting^{154,155}; however, one study suggested that hydrocortisone may be helpful.¹⁵⁶ Persistent hyponatremia can be treated by using mildly hypertonic solutions (1.25% to 2% saline) as the sole IV fluid. There may be a role for antidiuretic hormone (ADH) antagonists such as conivaptan,

but since they increase urine volume, extreme caution must be exercised to avoid hypovolemia.¹⁵⁷

Hypertension. Initial attempts to treat hypertension should include analgesics and nimodipine; other antihypertensive agents should follow if needed. Useful medications include intermittent doses of beta-blockers and vasodilators. If a continuous infusion is needed, nicardipine or clevidipine are effective. When significant hydrocephalus is present, hypertension should not be treated until after the hydrocephalus is addressed. This is because the hypertension may be acting to maintain adequate cerebral perfusion in the face of elevated ICP.

Magnesium Sulfate. Magnesium antagonizes calcium and, thus, can potentially reduce vasospasm. Almost 40% of patients with SAH have low serum magnesium levels on presentation, leading to speculation that the administration of magnesium may improve outcome of SAH patients. Advantages of magnesium include ease of administration, low cost, and favorable safety profile.¹⁵⁸ Several studies have suggested benefit,^{159,160} but controlled trials have been inconclusive.^{161,162} A recent meta-analysis of ten randomized trials of magnesium sulfate found no support for its use.¹⁶³

Statins. Statins may be beneficial in SAH through their ability to induce nitric oxide synthetase, leading to dilation of cerebral vessels, or via antiinflammatory effects. Some preliminary studies have suggested that they may reduce vasospasm and improve outcome,^{164,165} while others have not.¹⁶⁶⁻¹⁶⁸ Over 800 patients were enrolled in a multicenter phase III trial of simvastatin 40 mg or placebo, which found no short- or longer term benefit of the drug.¹⁶⁹

Management of Secondary Complications

Rebleeding. Multiple clinical trials have demonstrated that antifibrinolytic agents such as epsilon aminocaproic acid and tranexamic acid reduce the risk of rebleeding, but this benefit is offset by an increased incidence of vasospasm and hydrocephalus.^{170,171} With the advent of early intervention, the use of these agents has declined dramatically. More recently, there has been interest in a shorter course of antifibrinolytic therapy while awaiting surgery or endovascular treatment. Tranexamic acid begun immediately upon SAH diagnosis and continued only until the aneurysm was secured (always within 72 hours) reduced the risk of rebleeding from 10.8% to 2.4% and did not increase risk of DCI.¹⁷²

Other measures directed at prevention of rebleeding include avoiding situations that produce sudden changes in the transmural pressure across the wall of the aneurysm (i.e., sudden increases in arterial or venous pressure or decreases in ICP). Patients are placed on bed rest and stimulation minimized. Agitated patients should be carefully sedated and long-acting agents avoided. Measures should be taken to minimize cough and Valsalva maneuvers. Stool softeners are administered to avoid straining. The definitive way to prevent rebleeding is to repair the aneurysm by surgical or endovascular means. Endovascular techniques involving electrolytically detachable platinum coils that thrombose the aneurysm are now routinely used to repair acutely ruptured aneurysms (Fig. 53-9).

The International Subarachnoid Aneurysm Trial compared surgical clipping with endovascular coiling of acutely ruptured intracranial aneurysms. Patients were eligible to be enrolled only if there was clinical equipoise regarding the best method to repair the aneurysm. Initial results favored endovascular coiling, with 23.7% dead or dependent at 1 year versus 30.6% in the surgery group.¹⁷³ Long-term follow-up indicated a small increased risk of recurrent bleeding from a coiled compared to a clipped aneurysm. Regardless, at 5 years the risk of death remained significantly lower in the coiled group, but the proportion of survivors who were independent did not significantly differ.¹⁷⁴ Longer term follow-up was reported on 1644 patients 10-18.5 years after treatment, and the odds of death or dependency were greater in the surgical group. Rebleeding was more common after coiling, but the risk was small, and the probability of disability-free survival was significantly greater in the endovascular group at 10 years.

TABLE 53-2 Hunt and Hess Clinical Classification of Subarachnoid Hemorrhage

- I. Asymptomatic or mild headache and neck stiffness
- II. Moderate to severe headache and neck stiffness ± cranial nerve palsy
- III. Mild focal deficit, lethargy, or confusion
- IV. Stupor, moderate to severe hemiparesis

| III | 13 to 14 | Present |
| IV | 7 to 12 | Present or absent |
| V | 3 to 6 | Present or absent |

FIGURE 53-9 ■ Angiogram demonstrating middle cerebral artery aneurysm before (A) and after placement of detachable coils to thrombose the aneurysm (B).

Hydrocephalus. The decision to treat hydrocephalus is usually based on the CT appearance of enlarging ventricles in a patient whose level of consciousness is deteriorating. During placement of an EVD, the CSF pressure must be reduced slowly to lessen the risk of aneurysmal rerupture. CSF drainage may be needed for many days to clear intraventricular blood before it can be determined if a permanent shunt is required.

Delayed Cerebral Ischemia. Monitoring for DCI involves serial neurologic exams, serial transcranial Doppler (TCD) measurement of blood flow velocities,^{177,178} and catheter angiography. The use of CT angiography and CT perfusion for this purpose is growing. Neurologic signs may be vague, such as a global decline in responsiveness, or may be focal deficits. Symptoms may wax and wane, being exacerbated by hypovolemia or hypotension. Vasospasm can be identified on TCD by an increase in linear blood flow velocity (LBFV) and is defined as mild (>120 cm/sec), moderate (>160 cm/sec), or severe (>200 cm/sec).¹⁷⁹ Alternatively, the rate of rise in the LBFV is used to define the onset of vasospasm. The sensitivity of TCD in detecting vasospasm is about 80% when compared to angiography, at least partly because TCD samples only a small segment of the vasculature.¹⁸⁰ It has a negative predictive value, and the presence of normal velocities usually indicates the absence of vasospasm. Newer CT and MRI techniques including angiography and perfusion may have a future role in assessing for DCI.

When making a clinical diagnosis of DCI, alternative causes of neurologic changes such as sedatives, rebleeding, hydrocephalus, cerebral edema, metabolic derangements, and infections should be promptly excluded using radiographic, clinical, and laboratory assessments. Detection of clinical signs of DCI is particularly difficult in poor grade patients because of the limited exam that is possible. CT perfusion may aid in clinical decision making here.

Prevention. Routine measures taken to reduce risk of DCI include mechanical removal of subarachnoid blood at the time of aneurysm surgery or by CSF drainage, administration of the centrally acting calcium channel antagonist nimodipine, and avoidance of intravascular volume contraction or hypotension. Nimodipine (60 mg orally every 4 hours) for 3 weeks after SAH reduces the impact of symptomatic vasospasm and improves outcome.^{181,182} Its beneficial effect may be due to action on the cerebral vessels or by preventing calcium influx into ischemic neurons. Any hypotension developing with nimodipine use can usually be managed with fluids or by adjusting the dosage schedule to 30 mg every 2 hours. If the impact of nimodipine on blood pressure cannot be overcome in patients with DCI, it may have to be discontinued.

While there is general agreement that hypovolemia must be avoided, the use of prophylactic hypervolemia is more controversial.¹⁸³⁻¹⁸⁵

In a prospective controlled study, prophylactic volume expansion with albumin failed to reduce the incidence of clinical or TCD-defined vasospasm, did not improve CBF, and had no effect on outcome.¹⁸⁶ Costs and complications may be higher with the use of prophylactic hypervolemia.

Prophylactic use of transluminal balloon angioplasty was evaluated in a prospective, randomized controlled trial.¹⁸⁷ Although it reduced the need for therapeutic angioplasty and reduced ischemic deficits, these benefits were offset by procedure-related vessel complications.

Treatment of DCI. The trigger for instituting more aggressive interventions varies widely. Some centers actively intervene in the setting of rising TCD velocities¹⁸⁸ or angiographic vasospasm in asymptomatic patients,¹⁸⁹ whereas others institute aggressive measures in the setting of clinical deterioration. Aggressive measures include both hemodynamic and endovascular manipulations.¹⁹⁰⁻¹⁹² The goal is to improve CBF in ischemic regions. Since patients with SAH tend to become hypovolemic and lose pressure autoregulation,¹⁹³ it has been inferred that hypervolemia, induced hypertension, and augmentation of cardiac output would accomplish that goal.

Hemodynamic Augmentation. Hemodynamic interventions to improve CBF include hypervolemia, hypertension, and hemodilution, or “triple-H therapy.” Because of the risk of rebleeding, this therapy is reserved for patients who have had repair of the ruptured aneurysm. The presence of other small, untreated aneurysms does not exclude use of this therapy. Support for the benefit of hemodynamic augmentation is based on case series, and the relative contribution of each component is debated.

Data supporting the use of hypervolemia are scant. In one study of patients with symptomatic vasospasm, hypervolemia was reported to improve CBF, but a proper control group was not used.¹⁹⁴ Other studies question whether hypervolemia adds further benefit beyond correction of hypovolemia and report that the impact of volume expansion on CBF is modest compared to induced hypertension.¹⁹⁵

Hemodilution is perhaps the least understood component. The rationale is to augment CBF by reducing blood viscosity. The tradeoff is that oxygen-carrying capacity is reduced, reducing oxygen delivery. When studied in SAH patients, this was the case: while there was a rise in CBF, oxygen delivery fell following hemodilution.¹⁹⁶ For this reason, hemodilution has been abandoned.

More recently, use of blood transfusion in anemic patients has been suggested to improve cerebral oxygen delivery. Current recommendations are to maintain hemoglobin closer to 10 g/dL in patients at risk of ischemia (be it cardiac or cerebral) rather than use the standard transfusion threshold of hemoglobin of 7 g/dL.

FIGURE 53-10 ■ Example of severe distal internal carotid and proximal middle cerebral artery vaso-spasm before (A) and after (B) angioplasty.

Blood pressure augmentation with dopamine and phenylephrine has been reported to modestly increase CBF, although the optimal target has not yet been identified.¹⁹⁵ Dobutamine and milrinone may be effective in improving cardiac output and CBF in some patients. In a retrospective comparison of the impact of hypervolemia, hypertension, and transfusion of 1 unit of red blood cells on cerebral oxygen delivery measured by PET in anemic patients, transfusion produced the biggest response.¹⁹⁷

The initial step is to rapidly correct any possible hypovolemia with isotonic crystalloid or colloid fluids. If there is no immediate response, vasoactive agents are instituted—vasopressors (phenylephrine, norepinephrine) or, alternatively, inotropes (dobutamine, milrinone).

Recently, there has been a decline in the use of Swan-Ganz catheters to manage hemodynamic augmentation. The arbitrary pulmonary capillary wedge pressure goals used in the past have been abandoned. Fluid administration should be adjusted to optimize cardiac output. Goals for blood pressure should be defined as a percent change from baseline (beginning with an approximately 15% change) rather than prespecified levels. The degree of hemodynamic augmentation should be titrated continuously to the patient's neurologic status; thus, if a goal is reached but there is no neurologic improvement, the goal should be modified. Once the optimal goals have been reached, they are usually maintained for 2 to 3 days and then gradually weaned, guided by neurologic status.

Anemia may contribute to DCI. While transfusion can have beneficial effects on brain physiology, it may be associated with medical complications, infection, vasospasm, and poor outcome after SAH. Still, given the high risk of ongoing cerebral ischemia, the results of the Transfusion Requirements in Critical Care Trial and subsequent observational studies on red blood cell transfusion in general critical care should not be applied to SAH patients, as with patients with cardiac ischemia.¹⁹⁸ Practice surveys indicate that transfusion thresholds of 8 to 10 g/dL are commonly used, with the higher range reserved for patients with DCI.

Endovascular Treatments. The endovascular approach to vasospasm involves treatment of constricted vessels with either balloon angioplasty or intraarterial infusion of vasodilating agents.^{151,199}

Angioplasty on the proximal segments of vasospastic cerebral vessels yields impressive sustained angiographic changes (Fig. 53-10).^{200,201} Vasoconstriction in more distal vessels usually cannot be reached by angioplasty catheters and can be treated with intraarterial infusion of vasodilators. Intraarterial papaverine rapidly dilates the entire cerebral vasculature, but reversal of clinical deficits is inconsistent.²⁰²⁻²⁰⁴ Its use has largely been abandoned because of its short-lived effect and complications, including increased ICP, apnea, worsening of vasospasm, neurologic deterioration, and seizures.²⁰⁵ It has been replaced by nicardipine, verapamil, nimodipine, and milrinone.²⁰⁶⁻²⁰⁸

The timing of when to initiate endovascular therapy is debated. It is generally used if, after a few hours, the response to hemodynamic augmentation is inadequate, but it may be the initial therapy in patients with poor cardiac function who are at high risk of complications of hemodynamic manipulation.²⁰⁹

Endothelin-1 Antagonists. Endothelin-1 (ET-1) is a 21-amino acid peptide that mediates vasoconstriction. In early studies, an endothelin antagonist clazosentan reduced angiographic vasospasm^{210,211} and tended to reduce vasospasm-related morbidity/mortality. Subsequently, two very large randomized controlled trials confirmed the reduction in angiographic vasospasm, but clazosentan did not change clinical outcome.²¹²

Fever. After SAH, fever develops in well over half of patients and is associated with increased length of stay, worse outcome, and higher mortality. Early in the disease course, most fevers are central in origin. Antipyretics are effective in a minority of patients, although intravenous forms may be more effective. Surface and intravascular cooling devices are much more effective, but benefits from cooling may be offset by negative consequences from shivering.²¹³

Prognostic Factors and Causes of Mortality

Untreated aneurysmal SAH carries a poor prognosis, with an estimated mortality rate of about 50%. Of those who make it to medical attention, mortality is 20% to 40%. Causes of death are about equally distributed among direct effects of the initial hemorrhage, rebleeding, vasospasm, and medical complications. Overall, less than one-third of patients achieve good neurologic recovery. Predictors of poor

prognosis include loss of consciousness or poor neurologic condition (i.e., high Hunt and Hess grade) on admission, older age, hypertension, preexisting medical illness, ≥ 1 mm thickness of subarachnoid blood on CT (Fisher grade 3), seizures, cerebral edema, aneurysm location in the basilar artery, and symptomatic vasospasm.²¹⁴⁻²¹⁸ Scales

quantifying degree of physiologic illness are also predictive of outcome in patients with SAH.²¹⁹ Long-term survivors of the initial hemorrhage continue to suffer a 3% annual risk of rehemorrhage unless the aneurysm is repaired.

KEY POINTS

Intracerebral Hemorrhage

1. Intracerebral hemorrhage (ICH) primarily injures the brain through direct mechanical compression and not ischemia.
2. Early hematoma expansion occurs in over one-third of patients who present within 3 hours and is the primary cause of early neurologic deterioration. Early treatment of hypertension and correction of coagulopathy may help limit expansion.
3. Open surgical hematoma evacuation and corticosteroid treatment have failed to show a benefit. The efficacy of osmotic agents has not been adequately evaluated.
4. Minimally invasive surgery combined with instillation of t-PA into the hematoma is promising, and a pivotal trial is under way.
5. The most common cause of death after ICH is withdrawal of life-sustaining interventions, followed by transtentorial herniation and medical complications of immobility.

Subarachnoid Hemorrhage

1. Subarachnoid hemorrhage (SAH) typically presents as the sudden onset of a severe headache, often with nausea, vomiting, and syncope. Focal neurologic deficits are uncommon.
2. Rebleeding, which is often fatal, occurs most commonly within the first 24 hours. It can be prevented by early surgical or endovascular repair of the aneurysm.

3. Hydrocephalus may develop acutely within hours of SAH or gradually up to weeks later and usually manifests as an insidious decline in mental status.
4. Delayed angiographic vasospasm occurs in more than two-thirds of patients, especially those with large amounts of subarachnoid blood. About one-third of patients develop delayed cerebral ischemia, which can cause focal neurologic deficits and infarction. Management options include nimodipine, hemodynamic augmentation, and endovascular maneuvers.
5. Management of SAH-associated "cerebral salt wasting" often requires the administration of large volumes of isotonic saline to prevent intravascular volume contraction and restriction of free water and mildly hypertonic saline solutions to treat hyponatremia.
6. Cardiac abnormalities, including electrocardiographic changes, mildly elevated cardiac enzymes, and arrhythmias, are common after SAH and are thought to be related to elevated catecholamine levels rather than myocardial ischemia. Rarely, a more extreme form of cardiac dysfunction occurs at the time of hemorrhage with cardiomyopathy, hypotension, and pulmonary edema.

The routine use of continuous electroencephalographic (cEEG) recordings in intensive care demonstrates that clinical seizures in critically ill patients, both with neurologic and nonneurologic conditions, are the tip of the iceberg regarding seizure frequency in this vulnerable population. Nonconvulsive seizures are detected in 10% to 30% of critically ill patients with altered mental status and in up to 60% of critically ill patients who have been witnessed to have prolonged clinical seizures earlier during their hospital stay.¹ The presence of seizures in this population is associated with worse functional outcome at discharge,² multiple markers of disease severity,³ and long-term neurologic injury.⁴ The routine use of cEEG monitoring and quantitative EEG (qEEG) analysis leads to the diagnosis of electrographic seizures and timely modification of treatment,⁵ which may affect early- and long-term disability and mortality. The use of cEEG has become standard care in the intensive care unit (ICU). Its use is strongly recommended in cases of recent status epilepticus, unexplained coma, altered mental status, and behavioral changes and also in most patients with intracranial hemorrhage, as these cases are more likely to be associated with subclinical seizures.¹

Among patients without primarily neurologic conditions, the presence of a seizure may be the first indication of a central nervous system (CNS) complication; delay in recognition and treatment of seizures is associated with an increased risk of mortality.⁶ Thus, rapid diagnosis, treatment, and follow-up of epileptic activity and seizures is crucial. In addition, since epilepsy affects around 2% of the population, patients with a predisposition to seizures may enter the ICU for treatment of other systemic problems. These patients are at high risk for developing seizures and status epilepticus in the context of acute or severe illness.⁷ Patients developing status epilepticus often require critical care management as treatment escalates to include multiple antiseizure medications and sedatives that require airway protection, hemodynamic support, and close monitoring.

Status epilepticus refers to prolonged seizure activity beyond the usual duration of a self-limited, isolated seizure; it may be the primary indication for admission to the ICU, or it may occur in ICU patients. Seizures that persist longer than 5 minutes or recurrent seizures without recovery to the patient's neurologic baseline between seizures should be considered and treated as status epilepticus.⁸ Status epilepticus can also be subclinical, with little or no overt signs of seizures. Of patients monitored with EEG as part of a coma evaluation, 8% to 10% were reported to be in nonconvulsive status epilepticus (NCSE).⁹

Recognizing the risk factors, clinical presentation, diagnosis, and management of clinical and subclinical seizures in the ICU is a frequent task for the intensivist. Recent technologic advances enormously facilitate the diagnosis and follow-up of these patients in real time. Communication between the ICU team and the neurology/neurophysiology team is crucial to offer the patient timely therapy that significantly affects outcome.⁶

EPIDEMIOLOGY

Limited data are available on the epidemiology of seizures in the ICU. A 10-year retrospective study of all ICU patients with seizures revealed that 7 patients had seizures per 1000 ICU admissions.¹⁰ A 2-year prospective study of medical ICU patients identified 35 with seizures per 1000 admissions.¹¹ In a retrospective analysis of 570 patients undergoing continuous EEG monitoring, seizures were detected in 110 patients

(19%). Of those patients with seizures, the majority were in ICUs at the time of the EEG (n = 101; 89%). In this series, 92% of the recorded seizures were nonconvulsive, requiring EEG for the diagnosis.¹²

Up to 34% of hospital inpatients experiencing a seizure die during their hospitalization.¹¹ In a study of medical ICU patients, having even one seizure while in the ICU for a nonneurologic reason doubled in-hospital mortality.¹¹ Incidence estimates for status epilepticus in the United States and Europe vary from 10.3 to 41/100,000.^{3,13,14,15} The incidence has a bimodal distribution, peaking in young children and in the elderly.^{16,13} Mortality estimates vary widely, but data suggest that prolonged seizure duration is a negative prognostic factor. For patients whose generalized convulsive status epilepticus (GCSE) resolves within 30 to 59 minutes, the reported mortality is 2.7%, whereas patients seizing for more than 60 minutes have a mortality of 32%.¹⁷ If GCSE develops de novo in hospitalized patients, the mortality is 61%.¹⁸ For patients in NCSE, the mortality has been reported as high as 57%⁶ and correlates with the underlying cause, severe impairment of mental status, and the development of complications, especially respiratory failure and infection.¹⁹ Determining the contribution of status epilepticus to mortality is challenging due to the large impact of the underlying etiology on outcomes.

Table 54-1 summarizes the most common causes of status epilepticus in adults in the community. Almost 50% of the cases were attributed to cerebral vascular disease.²⁰ Antiseizure-drug noncompliance is the main cause of status epilepticus in patients with a previous history of epilepsy; CNS infection, stroke, and metabolic disturbances predominate in patients without previous seizures.⁷

Limited data are available concerning the functional abilities of GCSE survivors, and no data reliably permit distinction between the effects of status epilepticus and the effects of its causes. GCSE has the worst prognosis for neurologic recovery. Causes associated with increased mortality include anoxia, intracranial hemorrhages, tumors, infections, and trauma. In addition, intellectual ability declines as a consequence of status epilepticus.²¹ Survivors of status epilepticus often have memory and behavioral disorders out of proportion to the structural damage produced by the cause of their seizures. Case reports of severe memory deficits after prolonged complex partial status epilepticus have been published.²² Conversely, one prospective study of 180 children with febrile status epilepticus reported no deaths or new cognitive or motor handicap.²³ Experimental animal²⁴ and human epidemiologic²⁵ studies suggest that status epilepticus may be a risk factor in the development of future seizures. Whether treatment of prolonged seizures reduces the risk of subsequently developing epilepsy remains uncertain.

CLASSIFICATION

The most recent revision of the terminology and classification of seizures and epilepsy from the International League Against Epilepsy (ILAE) was published in 2010.²⁶ This new terminology abandons concepts such as dichotomous simple versus complex partial seizures, which implied the existence of only two possible states of awareness during seizures, in favor of more descriptive terms that may better represent the multiple possibilities of awareness, levels of interaction, responsiveness, and recollection seen in focal epileptic seizures (Table 54-2). The concept of focal and generalized seizures remains but is reinterpreted as the understanding of the pathophysiology of epilepsy

evolving away from a pure localization paradigm and more toward an understanding of cortical networks.

Focal seizures are defined by the presence of an epileptogenic network confined to one hemisphere or a single brain lobe; in generalized seizures, the epileptogenic network has bilateral hemispheric representation. These terms continue to be used in relation to the description of the clinical seizure initiation and presentation.

The new terminology emphasizes the etiology of epilepsy in three main groups: genetic, structural-metabolic, and unknown. These groups allow for epilepsy syndromes to move from one group to another as further research elucidates better understanding of specific clinical conditions over time. Electroclinical epilepsy syndromes remain at the core of the classification, in the hopes that their identification and study will advance our understanding of these conditions. The classification of nonsyndromic epilepsies in the structural-metabolic and unknown categories remains in place and acknowledges the value of semiology, EEG, and imaging in establishing the localization and classification of the epilepsy type and origin. Careful description of the phenomenology of seizures, etiology, and localization are emphasized as an important part of the patient's care.

Seizures are the clinical manifestation of the underlying predisposition for abnormal excessive and synchronous brain activity that defines epilepsy. Seizures can affect all measurable brain functions and follow a predictable clinical presentation largely related to the site of origin of the epileptic activity and the pattern of propagation. The identification of clean semiological descriptions and findings is challenging in the ICU, except for observation of motor manifestations. ICU patients often have altered awareness and a decreased level of interaction due

to medications, hypotension, sepsis, or intracranial lesions; thus, the presentation of focal seizures may be difficult to establish by observation alone. Modifiers to the description of focal or generalized seizures have been included in the classification (Table 54-3) and can be applied to focal and generalized seizures and to status epilepticus. Seizure classification is based on the combination of the seizure description and modifiers. An ICU patient who has continuous, regular repetitive contractions in a stable muscle group in the right arm while awake and responsive can be classified as having focal right arm clonic status epilepticus without impairment of consciousness or awareness.

Epilepsia partialis continua, a special form of focal status epilepticus in which repetitive movements of epileptic origin affect a small area of the body, can sometimes continue relentlessly for months or years.

The ILAE continues to work toward revising and updating the current classification system. For the most recent information regarding this ongoing project, refer to www.ilae.org.²⁷

PATHOGENESIS AND PATHOPHYSIOLOGY

The causes and effects of status epilepticus at the cellular, brain, and systemic levels are interrelated, but their individual analysis is useful for understanding them and their therapeutic implications. The ionic events of a seizure follow the opening of ion channels coupled to excitatory amino acid receptors. From the standpoint of the intensivist, three channels are important, as their activation may raise intracellular free calcium to toxic levels: alpha-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid receptor (AMPA), *N*-methyl-D-aspartate receptor

(NMDAR), and metabotropic channels. These excitatory amino acid systems are crucial for learning and memory. Counterregulatory ionic events are triggered by the epileptiform discharge as well, such as the activation of inhibitory interneurons suppressing excitatory neurons via ionotropic γ -aminobutyric acid (GABA_A) synapses.

The cellular effects of excessive excitatory amino acid channel activity include the following: (1) generation of toxic levels of intracellular free calcium; (2) activation of autolytic enzyme systems; (3) production of oxygen free radicals; (4) generation of nitric oxide, which both enhances subsequent excitation and serves as a toxin; (5) phosphorylation of enzyme and receptor systems, making seizures more likely; and (6) an increase in intracellular osmolality, producing neuronal swelling. If adenosine triphosphate production fails, membrane ion exchange ceases, and neurons swell further. These events produce the neuronal damage associated with status epilepticus. Longer status epilepticus duration produces profound alterations and an increasing likelihood of becoming refractory to treatment.²⁸

Many other biophysical and biochemical alterations occur during and after status epilepticus. The mechanisms by which status epilepticus damages the nervous system have been reviewed.^{29,30} Absence status epilepticus is an exception; it consists of rhythmically increased inhibition and does not appear to produce clinical or pathologic abnormalities.³¹

The electrical phenomena of status epilepticus seen in the scalp EEG reflect the seizure type (e.g., absence status epilepticus begins with a 3-Hz spike-and-wave pattern). The sustained depolarizations that characterize status epilepticus alter the extracellular milieu, raising extracellular potassium, which subsequently exceeds the buffering ability of astrocytes.

The increased cellular activity of status epilepticus increases oxygen and glucose demands, and cerebral blood flow initially increases. After about 20 minutes, however, energy supplies are exhausted, causing local catabolism to support ion pumps, which is thought to be a major cause of epileptic brain damage. GCSE also produces life-threatening systemic effects.³² Excess secretion of epinephrine and cortisol cause systemic and pulmonary arterial pressures to rise dramatically at seizure onset and produce hyperglycemia. Muscular work accelerates heat production, increases core body temperature, and raises blood lactate levels. Airway obstruction and abnormal diaphragmatic contractions impair respiration. Carbon dioxide production increases markedly while excretion falls. The combined respiratory and metabolic acidosis frequently reduces the arterial blood pH to 6.9 or lower. The associated hyperkalemia has deleterious effects on cardiac electrophysiology and may propagate seizure activity. Coupled with hypoxemia and the elevation of circulating catecholamine levels, these conditions can produce cardiac arrest. Neurogenic pulmonary edema is the likely cause of death in many cases. Rapid termination of seizure activity is the most appropriate treatment; the restitution of ventilation and the metabolism of lactate quickly restore a normal pH.

After about 30 minutes of continuous convulsions, motor activity may diminish while electrographic seizures persist. Hypotension and hyperthermia ensue, and gluconeogenesis can fail, resulting in hypoglycemia. GCSE patients often aspirate oral or gastric contents, producing chemical pneumonitis or bacterial pneumonia. Rhabdomyolysis is common and may lead to renal failure. Compression fractures, joint dislocations, and tendon avulsions are other serious sequelae.

The mechanisms that terminate seizure activity are poorly understood. Leading candidates are inhibitory mechanisms, primarily GABAergic interneurons and inhibitory thalamic neurons.

CLINICAL MANIFESTATIONS

The ICU environment poses a challenge to early seizure recognition because of multiple factors: (1) the occurrence of nonconvulsive seizures in patients with impaired awareness, (2) the occurrence of seizures in patients receiving neuromuscular blockade and/or sedation, and (3) misinterpretation of nonepileptic abnormal movements and behaviors as seizures. ICU patients often have depressed consciousness

in the absence of seizures owing to their disease, its complications (such as hepatic³³ or septic³⁴ encephalopathy), or drug administration. A further decline in alertness may reflect a seizure, but unless actions are taken to make this diagnosis, seizures and even status epilepticus may go unrecognized.

Patients receiving neuromuscular blocking agents do not manifest motor signs of seizures. Patients with increased intracranial pressure (ICP) from primary brain injury, hepatic encephalopathy, or other critical illnesses may be both paralyzed and sedated, making identification of seizures challenging in the absence of EEG monitoring. Tachycardia, tachypnea, and hypertension are signs of seizure that can be misinterpreted as evidence of inadequate sedation or primary cardiorespiratory conditions.

Seizures are the second most frequent neurologic complication after encephalopathy in critically ill patients with non–primarily neurologic conditions,¹¹ making it imperative for ICU providers to be able to identify and suspect the presence of seizures in all patients with altered awareness in the ICU setting.

Generalized motor seizures and convulsive status epilepticus are more common in patients with a prior history of epilepsy in relation to acute illness or medication nonadherence. However, even among patients without a history of epilepsy, subtle clinical seizures and NCSE are increasingly recognized in the context of systemic illness or acute brain injury. Nonconvulsive seizures and NCSE occur in 10% to 30% of patients with altered mental status in the ICU. Risk factors include the presence of CNS infection (meningitis or encephalitis) and focal lesions such as a brain tumor or an area of encephalomalacia. Seizures in the ICU are often subtle and may be related to the anatomic location of the brain lesion. Minor twitching of the face or extremities, fluctuating levels of awareness or level of interaction, nystagmus or eye deviation, abnormal orofacial movements, and repetitive blinking are more commonly seen than generalized convulsive events. Continuous EEG monitoring is warranted in this population if seizures are suspected, since a delay in the diagnosis and treatment of NCSE likely leads to worse functional prognosis at discharge and increased mortality.³⁵

Patients with metabolic disturbances, anoxia, and other types of CNS injuries may demonstrate abnormal movements that can be mistaken for a seizure. Asterixis is a brief asynchronous loss of tone at the wrist or hip joints that can appear in the setting of metabolic encephalopathy. Stimulus-sensitive massive myoclonus after anoxia can be dramatic but usually self-abates in a few days. Controversy exists as to the epileptic origin of this disorder, and post-anoxic myoclonus has been reported in the presence of almost total cortical suppression.³⁶ Brain-injured patients may manifest paroxysmal sympathetic hyperactivity and associated rigidity or extensor posturing.³⁷ Patients with tetanus are awake during their spasms and flex rather than extend their arms as seizure patients do. Psychiatric disturbances in the ICU occasionally manifest as psychogenic nonepileptic events. As these events tend to cluster and manifest as dramatic convulsive episodes, they are often treated in the emergency department as refractory status epilepticus, which may prompt ICU admission. The clinical manifestations of seizures and status epilepticus depend on the type and the cortical area of abnormality. Tables 54-2 and 54-4 present the classification of epileptic seizures recognized by the ILAE; all of these may be seen in the ICU.

Convulsive seizures or status epilepticus are described when the main characteristic of the seizures is a motor phenomenon. The primary motor manifestations can be described as tonic when there is a sustained muscle contraction of a group of muscle in a regional or generalized distribution. Tonic seizures are often associated with a vibration or tonic tremor, focal tonic seizures can be followed by versive seizures in which there is a forced, sustained, and unnatural rotation of the head or the eyes to one side and away from the midline. Clonic seizures are regular, predictable, rhythmic, and repetitive contractions of a muscle group. Myoclonic seizures are brief, involuntary muscle contractions; they are unpredictable and irregular. Motor seizures can manifest in any combination of the described motor

phenomena, in any order; they can involve the axial muscles and extremities from the beginning of the seizure without warning, or they can start regionally in one body part and progress into a generalized motor seizure.

When a patient with GCSE is treated with antiseizure drugs in inadequate doses, visible convulsive activity may stop, but the electrochemical seizure continues. A prospective evaluation of 164 patients showed that nearly half manifested persistent electrographic seizures in the 24 hours after clinical control of convulsive status epilepticus.³⁸ Thus, EEG monitoring after control of convulsive status epilepticus is essential in directing therapy.³⁹

Patients typically begin to awaken within 15 to 20 minutes after the successful termination of status epilepticus; many regain consciousness much faster. Patients who do not start to awaken after 20 minutes should be assumed to have entered NCSE. Careful observation may disclose slight motor activity as described above. However, patients may present in NCSE without an inciting episode of GCSE. Failure to recognize NCSE is common in patients presenting with nonspecific neurobehavioral abnormalities such as delirium, lethargy, bizarre behaviors, cataplexy, or mutism.⁴⁰ A high suspicion of this disorder should be maintained in ICU patients with unexplained alteration of consciousness or cognition.

■ DIAGNOSTIC APPROACH

Observation is very important when a patient has a single clinical seizure, as this is the time to collect evidence of a focal onset suggestive of structural brain disease. The postictal examination is similarly valuable; language, motor, sensory, or reflex abnormalities after an apparently generalized seizure may uncover evidence of focal pathology.

Seizures in ICU patients have several potential causes that must be investigated. Drugs are a major cause of ICU seizures, especially in the setting of diminished renal or hepatic function or when the blood-brain barrier is breached. Imipenem-cilastatin⁴¹ and fluoroquinolones⁴² can lower the seizure threshold, especially in patients with renal

dysfunction. They should be avoided in patients at risk for seizures. Other antibiotics, especially β -lactams, are also implicated.⁴³ Sevoflurane, a volatile anesthetic agent, is dose-dependently epileptogenic in patients with no predisposition to seizures.⁴⁴

Recreational drugs are overlooked offenders in patients presenting to the ICU. Acute cocaine or methamphetamine intoxication is characterized by a state of hypersympathetic activity followed by seizures.⁴⁵ Although ethanol withdrawal is a common cause of seizures, discontinuing any hypnotic agent may prompt convulsions 1 to 3 days later. Narcotic withdrawal may produce seizures in the critically ill.¹¹ In the absence of a structural etiology for the seizure, complete toxicologic, infectious, and metabolic screening should be performed.

Serum glucose, electrolyte concentrations, and serum osmolality should also be measured. Nonketotic hyperglycemia^{46,47} and hyponatremia can precipitate both focal and generalized seizures. Seizure activity may infrequently be the first presenting sign of diabetes mellitus. Hypocalcemia rarely causes seizures beyond the neonatal period; its identification on analysis must not signal the end of the diagnostic workup. Hypomagnesemia has an equally unwarranted reputation as the cause of seizures in malnourished alcoholic patients.

The physical examination should emphasize assessment for both global and focal abnormalities of the CNS. Evidence of cardiovascular disease or systemic infection should be sought and the skin and fundi examined closely. The need for imaging studies should be addressed as soon as the clinical seizure is controlled. The management of epileptic seizures and convulsive status epilepticus should not be delayed by the need to obtain images or neurophysiologic data. If possible, treatment and diagnostic strategies should be instituted simultaneously. A prospective study in medical ICU patients determined that 38 of 61 patients (62%) had a vascular, infectious, or neoplastic explanation for their seizures.¹¹ Magnetic resonance imaging (MRI) should be performed on all ICU patients with new-onset seizures. Many ICP monitors are compatible with MRI. Patients who need cerebrospinal fluid analysis always require imaging of the brain first. When CNS infection is suspected, empiric antibiotic treatment should be started while these studies are being performed.

EEG is a vital diagnostic tool for evaluating patients with diagnosed or suspected seizures. Focal seizures usually show EEG abnormalities that begin in the region of cortex that produces seizures. Primary generalized seizures show bilateral hemispheric involvement from the onset. Postictal slowing or an asymmetric EEG amplitude provides clues as to the focal cause of the seizures, and epileptiform activity helps classify the type and origin of epileptic activity and may guide treatment. An emergency EEG is necessary to exclude NCSE soon after clinical seizures have apparently been controlled (Fig. 54-1).

Continuous EEG can help establish the diagnosis, frequency, localization, and duration of seizures. It also aids in the evaluation of the response to treatment and degree of encephalopathy. It offers continuous and often long-term data and real-time feedback that can be lifesaving in the ICU, with few added risks or costs to the patient.⁴⁸ Given the high prevalence of NCSE in this patient population and the low relative risks associated with cEEG, a low level of suspicion should trigger such evaluation. The advent of modern techniques of EEG analysis and trend analysis as in qEEG are invaluable in the ICU, as they allow the reviewer to identify trends of electrographic activity over longer periods of time, identify subtle asymmetries, and aid in the identification and quantification of EEG seizures. The use of this technology has gained recent attention and interest from the EEG and the ICU community. Indications for cEEG include patients with altered mental status and history of epilepsy, fluctuating level of consciousness, acute brain injury, following convulsive status epilepticus, and abnormal stereotypical movements or behaviors. Other indications include assessing the level of sedation, vasospasm monitoring, and monitoring the response to antiepileptic medications or sedative weaning.⁴⁹ In the context of hypothermia after cardiac arrest, cEEG may provide prognostic information⁵⁰ and should be used throughout the cooling protocol and until rewarming has been completed. The value of cEEG in

the long-term evaluation of severe anoxic encephalopathy with or without myoclonus remains to be determined.

More than half of the seizures diagnosed in ICU patients with EEG monitoring are detected within the first 30 minutes of recording; a third of these patients are found to have interictal epileptiform discharges within the same period of time. The risk of seizures diminishes if no epileptiform abnormalities are seen within 2 hours.⁵¹ A routine EEG, however, may miss the chance to diagnose seizures in this population, and continuous EEG recording is recommended. The presence of NCSE, lateralized periodic discharges, generalized periodic discharges, and an abnormal EEG background is associated with worse outcomes.²

The interpretation of EEG findings seen in the ICU is challenging for neurophysiologists and clinicians alike. In an effort to unify criteria and establish the clinical significance of EEG patterns, the subcommittee of critical care monitoring of the American Clinical Neurophysiology Society has proposed a classification system for EEG patterns in patients with impaired consciousness.⁵² The classification system proposes descriptive grouping of EEG activity by location, periodicity, frequency, and morphology, followed by a series of modifiers (Table 54-3). The use of this system has been validated with acceptable interrater reliability. The use of standardized terminology will help advance research and establish clinical correlates that will affect ICU care.

■ MANAGEMENT APPROACH

Treating Isolated Seizures

Administering antiseizure drugs to an ICU patient experiencing one or a few seizures in the absence of structural CNS lesions requires consideration of a provisional cause, estimation of the likelihood of recurrence, and recognition of the utility and limitations of antiseizure drugs. For example, the occurrence of seizures during ethanol withdrawal does not necessarily indicate the need for chronic treatment. The patient may need prophylaxis against delirium tremens, but the few seizures themselves seldom require treatment. Patients with convulsions during barbiturate or benzodiazepine withdrawal, in contrast, should receive short-term treatment with a benzodiazepine to prevent status epilepticus. Prolonged or frequent seizures caused by metabolic disturbances can be treated temporarily with benzodiazepines while the abnormality is being corrected. For example, treatment of patients with focal seizures related to nonketotic hyperglycemia should be directed at correction of the hyperglycemia and hypovolemia rather than antiseizure drug therapy.⁴⁷ On the other hand, ICU patients with CNS disease who have even one seizure should be given chronic antiseizure-drug therapy. Initiating this treatment after the first *unprovoked* seizure may help prevent subsequent epilepsy,⁵³ although there is considerable difference of opinion regarding this concept.⁵⁴ If a critically ill patient's clinical condition would be seriously complicated by a convulsion, antiseizure drug therapy even after the first seizure may be vitally important.

In general, IV formulations are preferred for critically ill patients to avoid variability in drug absorption and metabolism. In the United States, IV formulations of levetiracetam, lacosamide, phenytoin/fosphenytoin, valproate, and phenobarbital are available.

Levetiracetam is a newer antiseizure drug that is being used increasingly in ICUs for seizure treatment and prophylaxis.⁵⁵ The recommended initial dose is 500 to 1000 mg per day every 12 hours. Monitoring of serum concentrations is not indicated. The efficacy of doses >3000 mg has not been established. Levetiracetam is efficacious against a wide variety of seizure types, is generally well tolerated, has minimal drug-drug interactions, and is not metabolized by the liver. Renal failure requires dose adjustments, and supplementary doses should be given after hemodialysis.

Lacosamide was approved as adjunctive therapy for focal onset seizures in adults in 2008 and is commonly used in ICUs given its efficacy and favorable side effect profile. It has a novel mechanism of action and has been studied for use in status epilepticus. The initial

dose is 100 mg twice a day, to be increased based on response and tolerability to a recommended dose of 150 to 200 mg twice a day. No target serum concentration has been established. It has no known drug-drug interaction, but dose adjustments for renal and hepatic impairment are recommended. It has not been studied in severe hepatic failure. The most common side effects include PR prolongation and hypotension.

Despite growing evidence of deleterious adverse effects on cognition, fever, and increased risk of poor outcome,^{56,57} phenytoin is still frequently selected for prophylaxis or treatment of seizures. It is indicated for all seizure types at a dose of 100 mg two to four times per day, with target serum levels of 10 to 20 µg/mL. Hypotension and arrhythmias may complicate IV administration. Because of the rare occurrence of third-degree atrioventricular block, an external cardiac pacemaker should be available when patients with known conduction abnormalities receive IV phenytoin. Phenytoin requires propylene glycol as a solvent, is highly protein bound, and free serum levels can vary widely depending on nutritional status. The phenytoin prodrug fosphenytoin is water soluble; local adverse effects are less common with fosphenytoin than with IV administration of phenytoin, although cardiovascular complications are just as frequent.^{58,59} Fosphenytoin is dosed by phenytoin-equivalent units, and no dosage adjustments are needed when converting patients from phenytoin to fosphenytoin. It is rapidly converted to phenytoin in vivo, and free phenytoin levels after fosphenytoin administration do not differ markedly from those of phenytoin. If seizures recur despite a serum phenytoin level of 10 to 20 µg/mL (corresponding to an unbound concentration of about 1 to 2 µg/mL if the albumin is normal), a second agent is typically required. Both renal and hepatic dysfunction interferes with metabolism and excretion of phenytoin; serum levels should be monitored closely. Adverse reactions to phenytoin and other antiseizure drugs have been reviewed elsewhere.⁶⁰

Due to its efficacy for generalized seizures, valproate may be the agent of choice for patients with a history of primary generalized epilepsy presenting with seizures. Caution is advised in patients with traumatic brain injury, as a trend toward higher mortality rates was seen in a trial of valproate versus phenytoin for prevention of post-traumatic seizures.⁶¹ The recommended starting dose is 10 to 15 mg/kg/day, targeting total serum concentrations of 50 to 100 µg/mL. Valproate is 80% to 90% protein bound and does not require dose adjustment in renal impairment. Lower doses should be used in hepatic impairment, and it is contraindicated in severe hepatic impairment. Side effects of chronic valproate therapy are numerous, including hyperammonemia, thrombocytopenia, hepatotoxicity, pancreatitis, as well as many drug-drug interactions.

Phenobarbital remains a useful antiseizure drug for patients who continue to have seizures or are intolerant of other antiseizure drugs. Initial dose recommendations are 1 to 3 mg/kg/day in one to two doses, with a target serum concentration of 20 to 40 µg/mL. Hepatic and renal dysfunction alter phenobarbital metabolism and require close monitoring of serum levels. Sedation is the major adverse effect; allergy to the drug occurs rarely.

Treating Status Epilepticus

The evaluation and management of status epilepticus has been reviewed recently.¹ The definition of status epilepticus has evolved to include continuous clinical and/or electrographic seizures lasting for 5 minutes or more, or recurrent seizures without recovery to the patient's neurologic baseline between seizures. Previous definitions included seizure activity lasting 30 minutes or more, but there is evidence that permanent neuronal injury may occur before this cut-off, and seizures lasting more than 5 minutes often do not stop spontaneously.¹

Figure 54-2 shows a management algorithm for status epilepticus, and Table 54-5 summarizes the management approach including details on drug administration.¹ Both GCSE and NCSE have been associated with increased morbidity and mortality and should be approached as neurologic emergencies. General ICU considerations include airway

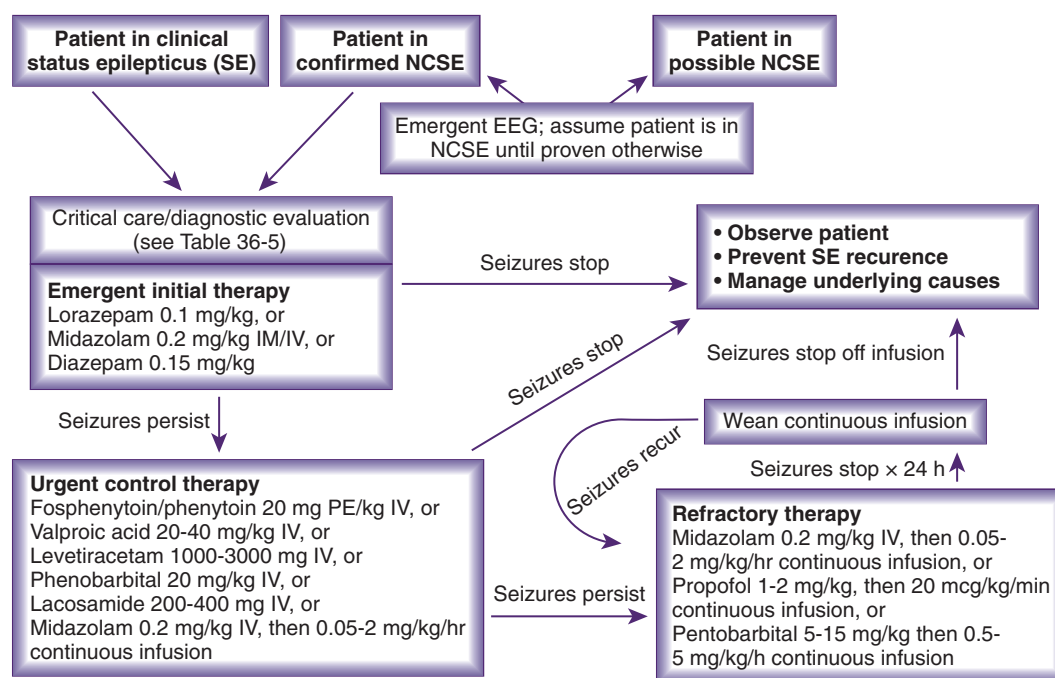

FIGURE 54-2 ■ Management algorithm for status epilepticus; NCSE, nonconvulsive status epilepticus; SE, status epilepticus.

protection, rapid exclusion of metabolic abnormalities (in particular, hypoglycemia), obtaining IV access, and ensuring hemodynamic stability. Antiseizure treatment should be initiated as soon as the diagnosis of status epilepticus has been established. The goal is the termination of clinical and electrographic seizure activity as soon as possible. The treatment approach has been subdivided into emergent initial therapy, urgent control therapy, and treatment of refractory status epilepticus.

Emergent initial therapy refers to the administration of first-line agents for termination of seizure activity. There is general consensus that benzodiazepines are the agents of choice as initial therapy. A large multicenter clinical trial compared multiple first-line regimens and found that the highest success rate was achieved with lorazepam.⁶² Preferred administration routes include IV (if IV access is available) and intramuscular (IM) injection, but buccal, nasal, or rectal routes are possible. Lorazepam is the agent of choice if IV access is available; midazolam is preferred for the IM route.⁶³ Diazepam is commonly used for rectal administration. Given the potential concern of respiratory depression with benzodiazepines, a randomized, controlled trial showed that patients treated with lorazepam had lower rates of respiratory or circulatory complications compared with placebo.⁶⁴ The initial dosing for lorazepam is 0.1 mg/kg IV, up to 4 mg per dose, which may be repeated after 5 to 10 minutes. Midazolam is given at a dose of 0.2 mg/kg IM or IV up to a maximum of 10 mg. Some advocate even higher doses for either of these benzodiazepines. In Europe, an IV formulation of clonazepam is available and has been used as emergent initial therapy. From a pharmacokinetic perspective, benzodiazepines are rapidly redistributed, resulting in a short duration of action. Hence, emergent initial therapy should be seamlessly followed by urgent control therapy that targets rapid attainment of therapeutic levels of conventional antiseizure drugs. If benzodiazepines fail to control seizures, urgent control therapy is initiated for seizure termination. If seizures are controlled by benzodiazepines, urgent control therapy targets prevention of seizure recurrence.

As with the treatment of isolated seizures in the ICU, IV formulation is preferred, especially since therapeutic drug levels can be achieved significantly faster. Phenytoin/fosphenytoin, valproate, levetiracetam, phenobarbital, and continuous infusion of midazolam have all been studied for urgent treatment. Additionally, lacosamide has emerged as an option to treat status epilepticus but has mostly been

investigated in refractory status epilepticus.^{65,66} Dosing of these drugs in status epilepticus is outlined in Table 54-5.

Refractory status epilepticus refers to status epilepticus that does not respond to a standard treatment regimen. There is controversy regarding this definition, but most experts agree that treatment has failed if seizures persist or recur after adequate doses of an initial benzodiazepine followed by one conventional antiseizure drug.¹ Continuous EEG monitoring is typically required to exclude ongoing electrographic seizure activity. It may be reasonable to attempt management of recurrent seizures with additional intermittent bolus therapy of alternate antiseizure drugs, provided the patient is clinically stable and has not required intubation for airway protection. Once it has been determined that intermittent bolus therapy has failed, treatment should be quickly escalated to a continuous infusion. The most commonly used drugs are midazolam, propofol, pentobarbital, and thiopental. Dosing recommendations are listed in Table 54-5. Patients who require any of these treatments will typically require mechanical ventilation and close cardiovascular monitoring. There is insufficient evidence to recommend any of these agents over another. Midazolam is the preferred agent at our institution because of its high efficacy in adults and children,^{67,68} its water solubility, and the lower incidence of cardiovascular adverse effects compared to pentobarbital or propofol. However, terminal half-lives of three to eight times normal have been reported with extended administration.⁶⁹ Propofol is reported to be effective in refractory status epilepticus, but comparisons with other agents have shown mixed results.^{70,71} Especially in younger patients, the risk of propofol-related infusion syndrome needs to be considered, particularly if high doses are required to control seizures. Severe hypotension is the most frequent side effect of pentobarbital therapy and is associated with increased mortality.⁷² Increases in nosocomial respiratory tract infection have been reported in patients treated with pentobarbital infusion.⁷³

Once clinical or nonconvulsive seizures have been controlled for about 24 to 48 hours, a gradual withdrawal of the continuous infusion should be initiated. If seizures recur upon withdrawal, the continuous infusion should be resumed until seizures are controlled. The addition of other antiseizure agents or other therapies such as hypothermia, immunomodulation, or neurosurgical resection of the seizure focus may be considered at that point.

TABLE 54-5 Treatment Approach to Status Epilepticus

Appropriate critical care treatment should be provided as soon as possible and simultaneously with emergent initial therapy for seizures. Treatment should be escalated quickly until seizures are controlled.

- 1a. Critical care treatment (dictated by clinical circumstances):
 - a. Intubation for airway protection and mechanical ventilation
 - b. Vital sign monitoring
 - c. Peripheral IV access
 - d. Treatment of hypotension with vasopressors
 - e. Finger stick blood glucose
 - f. Nutrient resuscitation (thiamine before dextrose)
 - g. Hypertension may be related to ongoing seizure activity and termination of status epilepticus often substantially corrects it. Additionally, many agents used to terminate status epilepticus can produce hypotension.
- 1b. Emergent initial therapy with benzodiazepines
 - a. Lorazepam 0.1 mg/kg up to 4 mg per dose, may repeat after 5-10 min
 - b. Midazolam 0.2 mg/kg IM/IV up to 10 mg
 - c. Diazepam 0.15 mg/kg up to 10 mg per dose, may repeat after 5 min
2. Urgent control therapy—antiseizure drugs available in IV formulations
 - a. Fosphenytoin/phenytoin 20 mg PE/kg IV, may repeat bolus of 5 mg/kg IV
 - b. Valproic acid 20-40 mg/kg IV, may repeat bolus of 20 mg/kg IV
 - c. Levetiracetam 1000-3000 mg IV
 - d. Phenobarbital 20 mg/kg IV, may repeat bolus of 5-10 mg/kg
 - e. Lacosamide 200-400 mg IV
 - f. Midazolam bolus 0.2 mg/kg IV, followed by 0.05-2 mg/kg/h continuous infusion
3. Refractory therapy—continuous infusion of antiseizure drugs, titrated to either seizure cessation, suppression-burst, or complete suppression on cEEG.
 - a. Midazolam bolus 0.2 mg/kg IV, followed by 0.05-2 mg/kg/h continuous infusion
 - b. Propofol bolus 1-2 mg/kg, followed by 20 mcg/kg/min continuous infusion, titrate up to 30-200 mcg/kg/min
 - c. Pentobarbital 5-15 mg/kg, may repeat bolus of 5-10 mg/kg, followed by 0.5-5 mg/kg/h continuous infusion
4. Treat complications

Complications of status epilepticus are numerous and can involve multiple organ systems. In particular, convulsive status epilepticus is associated with cardiac complications such as hypertension and tachycardia, as well as rhabdomyolysis and hyperthermia. Respiratory complications including respiratory failure, hypoxia, and neurogenic pulmonary edema may be seen. Status epilepticus is associated with neuronal damage and cerebral edema with increased intracranial pressure, which may require intracranial pressure monitoring and aggressive treatment with hypertonic agents.

KEY POINTS

1. Seizures and status epilepticus are common in ICU patients and are associated with high morbidity and mortality.
2. Observation is crucial when a patient has a single seizure. Post-ictal language, motor, sensory, or reflex abnormalities after a generalized seizure indicate focal pathology.
3. Seizures persisting longer than 5 minutes or two or more discrete seizures without neurologic recovery in between should be treated as status epilepticus. Patients who do not regain consciousness within 20 minutes after clinical seizure cessation should be considered to have entered NCSE, and cEEG monitoring is essential in directing the course of treatment.
4. The ICU patient with CNS disease who has even one seizure should be given chronic antiseizure drug therapy. This therapy should be reviewed before discharge.
5. Emergent initial therapy for treatment of status epilepticus is benzodiazepines (lorazepam, midazolam, diazepam) followed by urgent control therapy with IV formulations of levetiracetam, valproate, phenytoin/fosphenytoin, phenobarbital, or lacosamide. Status epilepticus refractory to an initial benzodiazepine and an appropriately chosen and dosed conventional antiseizure drug should be treated with continuous infusion of midazolam, barbiturates, or propofol.

Abnormal neuromuscular function may precipitate a patient's admission to an intensive care unit (ICU) or may develop as a consequence of another critical illness and its treatment. This chapter focuses primarily on respiratory failure due to neuromuscular disease but also addresses autonomic dysfunction that occurs in this setting. To facilitate the understanding of the concepts involved, a brief review of the motor unit and its physiology is provided, and the specific muscles critical to ventilation are identified.

■ THE MOTOR UNIT AND ITS PHYSIOLOGY

Central nervous system (CNS) activity designated for motor output is ultimately conducted by the lower motor neurons, also known as *alpha motor neurons*. A motor unit is composed of a lower motor neuron and its distal ramifications, its neuromuscular junctions, and the muscle fibers it innervates. The cell bodies of the lower motor neurons are located in the brainstem for cranial musculature and the anterior horn of the spinal cord for somatic muscles. Motor axons project through the subarachnoid space and penetrate the dura mater as nerve roots. They may join with other motor axons and with sensory and autonomic fibers in a plexus and then travel via the peripheral nerves to the muscles they innervate. Alpha motor neurons are myelinated, a feature that accelerates nerve impulse propagation. The multiple terminal ramifications of the motor neuron synapse on individual muscle fibers.

The motor axon communicates with muscle via a specialized area termed the *neuromuscular junction*. On the presynaptic side of the neuromuscular junction, the neurotransmitter acetylcholine is synthesized, packaged in vesicles, and stored for release. Depolarization of the axon opens the presynaptic voltage-gated calcium channels, which activate the molecular machinery responsible for drawing the vesicles to the presynaptic membrane. The vesicles then fuse with the membrane and release acetylcholine into the synaptic cleft. Acetylcholine molecules bind to receptors on the postsynaptic membrane and cause an influx of sodium, which in turn increases the muscle end-plate potential. When the end-plate potential exceeds the threshold level, the muscle membrane becomes depolarized. This depolarization releases calcium ions from the sarcoplasmic reticulum, and muscle contraction occurs through a process known as *excitation-contraction coupling*. After activating the acetylcholine receptor complex, the acetylcholine molecule is degraded by cholinesterase, and the presynaptic neuron then recycles the choline released by this reaction.

■ MUSCLES OF RESPIRATION

Three muscle groups may be defined based on their importance for respiration (Fig. 55-1):¹

1. *Upper airway muscles*: palatal, pharyngeal, laryngeal, and lingual
2. *Inspiratory muscles*: sternomastoid, diaphragm, scalenes, and parasternal intercostals
3. *Expiratory muscles*: internal intercostal muscles (except for parasternals) and abdominal muscles

The upper airway muscles receive their innervation from the lower cranial nerves. Sternomastoid innervation arrives predominantly from the cranial nerve XI, with a small contribution from C2. The phrenic nerve originates from cell bodies located between C3 and C5, with a

maximum contribution from C4, and innervates the diaphragm. Innervation to the scalenes arises from C4 to C8, whereas that of the parasternal intercostals is from T1 to T7. The intercostal muscles receive innervation from T1 to T12, and the abdominal musculature receives it from T7 to L1.

Clinical Presentation of Neuromuscular Respiratory Failure

Patients experiencing respiratory dysfunction due to neuromuscular disease typically present with a combination of upper airway dysfunction and diminished tidal volume (V_T). Upper airway muscle weakness typically presents with difficulty swallowing liquids, including respiratory secretions, as well as a hoarse or nasal voice. In addition to the risk of aspiration, these patients have difficulty with negative-pressure ventilation since the weakened muscles cannot keep the airway open as the pressure falls.²

Loss of V_T occurs secondary to weakness of the inspiratory muscles. In addition to diaphragmatic weakness, which may present with paradoxical abdominal movement,³ parasternal intercostal muscle weakness also causes diminished V_T by preventing the chest wall from expanding against negative intrapleural pressure. Thereby, lower cervical spinal cord injuries may induce respiratory failure despite preserved phrenic nerve function. As parasternal intercostal muscles develop spasticity over weeks, respiratory function of this type typically improves.

Patients with progressive generalized weakness (e.g., Guillain-Barré syndrome) commonly begin to lose V_T before developing upper airway weakness. To maintain minute ventilation and carbon dioxide excretion, a patient's respiratory rate increases. The respiratory rate is thus one of the most important clinical parameters to monitor. As the vital capacity falls from the norm of about 65 to 30 mL/kg, a patient's cough weakens, and clearing secretions becomes difficult. A further decrease in the vital capacity to 20 to 25 mL/kg results in an impaired ability to sigh, resulting in progressive atelectasis. At this point, hypoxemia may be present because of ventilation-perfusion mismatching, and an increasing percentage of V_T is used to ventilate dead space. Respiratory failure is imminent, and ICU admission is recommended for all patients with a vital capacity <20 mL/kg. The precise point at which mechanical ventilation is necessary varies with the patient, the underlying condition, and especially with the likelihood of a rapid response to treatment.

Regardless of the vital capacity, indications for intubation and mechanical ventilation include evidence of fatigue, hypoxemia despite supplemental oxygen administration, difficulty with secretions, and a rising PaCO₂. In the absence of hypercapnia, occasional patients (e.g., those with myasthenia gravis) can be managed with very close observation in an ICU with less invasive techniques (e.g., bilevel positive airway pressure [BiPAP]).⁴

In addition to vital capacity, trended measurements of the maximum inspiratory pressure (P_Imax, more typically recorded as a negative inspiratory force [NIF]), are useful indicators of ventilatory capacity. The inability to maintain a P_Imax greater than 20 to 25 cm H₂O usually indicates a need for mechanical ventilation. Although the maximum expiratory pressure (P_Emax) is a more sensitive indicator of weakness,⁵ it has not proven to be as useful as an indicator of the need for mechanical ventilation.^{6,7}

FIGURE 55-1 ■ Major respiratory muscles. Inspiratory muscles are indicated on the left, and expiratory muscles are indicated on the right. (From Garrity ER. Respiratory failure due to disorders of the chest wall and respiratory muscles. In: MacDonnell KF, Fahey PJ, Segal MS, editors. Respiratory intensive care. Boston: Little, Brown; 1987, p. 313.)

Since a patient with neuromuscular respiratory failure has an intact ventilatory drive,⁸ the fall in V_T is initially matched by an increase in respiratory rate, keeping the P_{aCO_2} normal or low until the vital capacity becomes dangerously reduced. Many patients initially maintain their P_{aCO_2} in the range of 35 mm Hg because of either (1) a subjective sense of dyspnea at low V_T or (2) hypoxia from atelectasis and increasing dead space. When the P_{aCO_2} begins to rise in these circumstances, abrupt respiratory failure may be imminent, as CO_2 displaces more oxygen from the alveolar gas. The modest degree of hypoxia in most of these patients worsens when the P_{aCO_2} begins to rise, displacing more oxygen from the alveolar gas. Moreover, aspiration pneumonia and pulmonary embolism are also frequent causes of hypoxemia in these patients. To determine the relative contributions of these conditions to a patient's hypoxemia, one can use a simplified version of the alveolar gas equation as follows (derived elsewhere)^{6,7}:

$$PAO_2 = PIO_2 - (P_{aCO_2}/R)$$

where PAO_2 is the alveolar partial pressure of oxygen, PIO_2 is the partial pressure of the inspired oxygen (in room air, 150 mm Hg), and R is the respiratory quotient (on most diets, about 0.8). This allows for the estimation of the alveolar-arterial oxygen difference ($PAO_2 - PaO_2$). Under ideal circumstances in young people breathing room air, this value is about 10 mm Hg, but it rises to about 100 mm Hg when the fraction of inspired oxygen (PIO_2) is 1.0. The alveolar air equation allows one to factor out the contribution of hypercarbia to the decrease in arterial partial pressure of oxygen (PaO_2); it should be used to determine whether there is a cause of significant hypoxemia in addition to the displacement of oxygen by carbon dioxide.

Physicians must observe patients for rapid, shallow breathing,⁹ recruitment of accessory muscles, and paradoxical movement of the abdomen during the respiratory cycle. Direct observation is particularly important as patients may have orbicularis oris weakness, causing an artificially low vital capacity and NIF measurements because they cannot form a tight seal around the spirometer mouthpiece. In addition to physical exam findings, fluoroscopy of the diaphragm is occasionally valuable for the diagnosis of diaphragmatic dysfunction.¹⁰

Autonomic dysfunction commonly accompanies some of the neuromuscular disorders requiring critical care, such as Guillain-Barré syndrome, botulism, and porphyria (Table 55-1). In Guillain-Barré

syndrome (discussed later) dysautonomia is common and may arise in parallel with weakness or may follow the onset of the motor disorder after 1 week or more.

■ NEUROMUSCULAR DISORDERS

Many chronic neuromuscular disorders and other CNS conditions affecting the suprasegmental innervation and control of respiratory muscles eventually compromise ventilation. In this chapter, we emphasize the more common acute and subacute neuromuscular disorders that precipitate or prolong critical illness due to ventilatory failure and autonomic dysfunction. A complete listing of neuromuscular diseases appears in Table 55-1; reviews of this subject^{11,12} and the references listed in Table 55-1 detail the more rare disorders. Some of the diseases listed (e.g., Lambert-Eaton myasthenic syndrome) rarely cause respiratory failure in isolation but may be contributing causes in the presence of other conditions,¹³ such as a neuromuscular junction blockade intended only for the duration of a surgical procedure.¹⁴

Neuromuscular Diseases Precipitating Critical Illness

Guillain-Barré Syndrome

Guillain-Barré syndrome, or acute inflammatory demyelinating polyradiculoneuropathy, is typically a motor greater than peripheral sensory neuropathy with subacute onset, monophasic course, and nadir within 4 weeks. Although the precise etiology is unknown, it is immune mediated and related to antibodies directed against peripheral nerve components. About 1.7 cases occur per 100,000 population annually.¹⁵ Most patients suffer from a demyelinating neuropathy, but in about 5% of cases, the condition is a primary axonopathy.¹⁶ Numerous antecedents have been implicated,¹⁷ the most common of which are listed in Box 55-1. The association with antecedent infections suggests that certain agents may provoke the production of antibodies that cross-react with peripheral nerve gangliosides. Ganglioside antibodies have been found in Guillain-Barré syndrome after *Campylobacter jejuni* infections, such as GM₁ antibodies in axonal forms¹⁸ and GQ_{1b} antibodies in the Miller-Fisher variant.¹⁹

TABLE 55-1 Neuromuscular Causes of Acute Respiratory Failure

| LOCATION | DISORDER | ASSOCIATED AUTONOMIC DYSFUNCTION? |
|------------------------|--|--|
| Spinal cord | Tetanus ¹¹⁹ | Frequent |
| Anterior horn cell | Amyotrophic lateral sclerosis ¹²⁰ | No |
| | Poliomyelitis | No |
| | Rabies | Frequent |
| | West Nile virus flaccid paralysis | No |
| Peripheral nerve | Guillain-Barré syndrome | Frequent |
| | Critical illness polyneuropathy | No |
| | Diphtheria | No, but cardiomyopathy and arrhythmias may occur |
| | Porphyria | Occasional |
| | Ciguatera (ciguatera poisoning) | Occasional |
| | Saxitoxin (paralytic shellfish poisoning) | No |
| | Tetrodotoxin (pufferfish poisoning) | No |
| | Thallium intoxication | No |
| | Arsenic intoxication ^{121,122} | No |
| | Lead intoxication | No |
| | Buckthorn neuropathy | No |
| Neuromuscular junction | Myasthenia gravis | No |
| | Botulism ¹²³ | Frequent |
| | Lambert-Eaton myasthenic syndrome ¹²⁴ | Yes, frequent dry mouth and postural hypotension |
| | Hypermagnesemia ¹²⁵ | No |
| | Organophosphate poisoning | No |
| | Tick paralysis | No |
| Muscle | Snake bite | No |
| | Polymyositis/dermatomyositis | No |
| | Acute quadriplegic myopathy | No |
| | Eosinophilia-myalgia syndrome ¹²⁶ | No |
| | Muscular dystrophies ¹²⁷ | No, but cardiac rhythm disturbances may occur |
| | Carnitine palmitoyl transferase deficiency | No |
| | Nemaline myopathy ¹²⁸ | No |
| | Acid maltase deficiency ¹²⁹ | No |
| | Mitochondrial myopathy ¹³⁰ | No |
| | Acute hypokalemic paralysis | No |
| | Stonefish myotoxin poisoning | No |
| | Rhabdomyolysis | No |
| | Hypophosphatemia ¹³¹ | No |

The initial findings of patients with Guillain-Barré syndrome are a subacute and progressive weakness, usually most marked in the legs, associated with sensory complaints but without objective signs of sensory dysfunction.²⁰ Deep tendon reflexes are often reduced or absent at presentation, though this finding may take several days to develop. The cerebrospinal fluid (CSF) typically reveals an albuminocytologic dissociation or elevated protein content without pleocytosis; however, this may not evolve until the second week of illness. The major reason to examine the CSF is to preclude other diagnoses. Although mild CSF lymphocytic pleocytosis (10-20 cells/mm³) may suggest the possibility of associated human immunodeficiency virus (HIV) infection, in most patients, the nucleated cell count is <10 cells/mm³.²¹ Although they may be normal initially, results of electrodiagnostic studies (motor and sensory nerve conduction studies and needle electromyography) often reflect segmental nerve demyelination with multifocal conduction blocks, temporally dispersed compound muscle action potentials, slowed conduction velocity, and prolonged or absent F waves.²² Diagnostic considerations for patients with suspected Guillain-Barré syndrome are primarily those listed in the Peripheral Nerve section of Table 55-1.

The components of treatment for patients with Guillain-Barré syndrome are as follows:

- Management of ventilatory failure
- Management of autonomic dysfunction
- Meticulous nursing care
- Psychological support
- Physical and occupational therapy
- Prevention of deep venous thrombosis
- Nutritional support

- Early planning for rehabilitation
- Immunotherapy for the underlying autoimmune condition

Patients with Guillain-Barré syndrome with evolving respiratory failure should be intubated when the vital capacity falls to about 15 mL/kg or when difficulty with secretions begins because the response to treatment is slow. If a patient has been immobile for several days before intubation and a neuromuscular junction blockade is needed, a nondepolarizing agent should be used to avoid transient hyperkalemia. Oral intubation is preferable to the nasal route because the tracheal tube is frequently required for a week or longer, raising the risk of sinusitis.

Many patients are too weak to trigger the ventilator, and in such cases, the assist/control or intermittent mandatory ventilation mode is initiated. Weaning patients with Guillain-Barré syndrome from mechanical ventilation must wait for an adequate improvement in strength reflected by a vital capacity of greater than 15 mL/kg and NIF greater than 25 cm H₂O. However, a formula using a combination of ventilatory and gas exchange variables may allow for a more accurate determination of a patient's ability to be weaned.²³ While pressure support ventilation is often used for weaning, evidence of its superiority over intermittent mandatory ventilation or synchronized intermittent mandatory ventilation modes is anecdotal. Most patients require mechanical ventilation for more than 4 weeks; however, as many as one-fifth need at least 2 months of support before they can breathe without assistance. Autonomic dysfunction typically presents as a hypersympathetic state and is often heralded by unexplained sinus tachycardia. The blood pressure may fluctuate wildly. Patients can also experience bradycardic episodes, which may require temporary pacing. Autonomic surges during tracheal suctioning or due to a

distended viscus may be very dramatic and should be minimized. Autonomic failure and pulmonary embolism are now the major causes of mortality in Guillain-Barré syndrome.

Nursing care for patients with Guillain-Barré syndrome is similar to that for other paralyzed and mechanically ventilated patients, but special care must be taken to remember that patients are completely lucid. In addition to explaining any procedures carefully, arranging for distractions during the daytime (e.g., television, movies, conversation, or visitors) and adequate sleep at night is very important. For the most severely affected patients, sedation should be considered. In concert with physical and occupational therapists, passive exercise should frequently be performed throughout the day.

Deep venous thrombosis is a significant danger. An episodic arterial desaturation is a common event, presumably owing to transient mucous plugging; therefore, submassive pulmonary emboli may be overlooked. Adjusted-dose heparin (to slightly prolong the partial thromboplastin time) should be given, and sequential compression devices should be used on the legs. Moreover, therapeutic anticoagulation may be considered. The risk of fatal pulmonary embolism extends through the initial period of improvement until the patients are ambulatory.

Nutritional support should begin as soon as a patient is admitted, with appropriate concern for the risk of aspiration.²⁴ Most mechanically ventilated patients with Guillain-Barré syndrome can be fed via soft, small-caliber feeding tubes; autonomic dysfunction affecting the gut occasionally requires total parenteral nutrition.

Immunotherapy for Guillain-Barré syndrome includes the removal of autoantibodies with plasma exchange or immune modulation with a high dose of intravenous immunoglobulin (IVIg). The efficacy of the plasma exchange has been evaluated in a Cochrane systematic review of six class II trials comparing plasma exchange alone with supportive care.²⁵ Most of the trials employed up to five plasma exchanges of 50 mL/kg over 2 weeks. In a large North American trial,²⁵ the time needed to improve one clinical grade (i.e., being weaned from the ventilator or being able to walk) was reduced by 50% in the plasma exchange group compared to the control group. There was no significant benefit when the plasma exchange commenced later than 2

weeks after the onset of symptoms. A meta-analysis revealed more rapid recovery in ventilated patients treated with a plasma exchange within 4 weeks of onset.²⁶ The optimal number of plasma exchanges has been assessed in patients with mild (unable to run), moderate (unable to stand without assistance), and severe (requiring mechanical ventilation) Guillain-Barré syndrome by the French Cooperative Group.²⁷ On the basis of this trial, two exchanges are better than none in mild Guillain-Barré syndrome; four are better than two in moderate Guillain-Barré syndrome; and six are no better than four in severe Guillain-Barré syndrome. Albumin is the preferred replacement solution.²⁸ Treatment with IVIg for Guillain-Barré syndrome has also been examined in a Cochrane systematic review. Five randomized controlled trials in adults showed that IVIg (0.4–0.5 g/kg over 4–5 days) is as effective as plasma exchange in Guillain-Barré syndrome patients with impaired walking.²⁹ IVIg is also more likely to be completed than plasma exchange; although the adverse events were not different. A large international multicenter randomized trial compared plasma exchange (50 mL/kg \times 5 exchanges over 8–13 days), IVIg (0.4 g/kg \times 5 days), and plasma exchange followed by IVIg.³⁰ No significant outcome differences between these therapies were found with respect to functional improvement at 4 or 48 weeks.

Evidence-based guidelines for Guillain-Barré syndrome immunotherapy have been published by the Quality Standards Subcommittee of the American Academy of Neurology.³¹ Plasma exchange is recommended for adult patients who cannot walk within 4 weeks of symptom onset. IVIg is recommended in these patients within 2 or possibly 4 weeks of symptom onset. Both treatments are deemed equivalent in efficacy, and combining treatment with plasma exchange and IVIg confers no additional benefit. In light of their therapeutic equivalence, the decision whether to employ plasma exchange or IVIg in treating acute Guillain-Barré syndrome may be determined by resource availability and by avoiding potential side effects related to a patient's medical comorbidities. Patients with heart disease, renal insufficiency or failure, hyperviscosity, or IgA deficiency may be more susceptible to complications of treatment with IVIg, whereas plasma exchange may be complicated in patients with labile blood pressure, septicemia, and significant venous access problems.

Despite the autoimmune pathophysiology of Guillain-Barré syndrome and the efficacy of corticosteroids in more chronic forms of inflammatory neuropathy, corticosteroids have not shown effectiveness in Guillain-Barré syndrome and are therefore not recommended.³¹ A large multicenter trial failed to demonstrate efficacy of high-dose intravenous methylprednisolone,³² and another large multicenter trial reported no added clinical benefit with the combined treatment of IVIg and methylprednisolone.³³

West Nile Virus Acute Flaccid Paralysis Syndrome

The large outbreak of West Nile virus encephalitis in the summer of 1999 in New York City marked the emergence of a relatively new cause of neuromuscular weakness with the potential for neuromuscular respiratory compromise. West Nile virus is a flavivirus transmitted by birds and mosquitoes. Humans may acquire West Nile virus from the bite of an infected *Culex* species mosquito, and a corresponding peak in human disease occurs in the late summer and fall. West Nile virus may also be transmitted to humans by organ transplantation,³⁴ blood and blood product transfusion,³⁵ transplacental exposure,³⁶ breastfeeding,³⁷ and percutaneous laboratory injuries.³⁸ About 20% of humans experience a mild flulike illness lasting 3 to 6 days, and about 1 in 150 develops CNS disease, which usually presents as meningoencephalitis.³⁹

In the initial North American outbreak of West Nile virus, about 10% of infected patients experienced flaccid weakness with clinical features resembling Guillain-Barré syndrome.⁴⁰ Although patients with West Nile virus infection exhibit a spectrum of clinical weakness,^{41,42} the most prominent and distinctive syndrome documented in several subsequent reports of West Nile virus infection is an acute “poliomyelitis-like” or acute flaccid paralysis syndrome with pathology localized to the ventral horns of the spinal cord and/or ventral

roots.⁴³⁻⁴⁹ These relatively younger patients developed acute, asymmetric, flaccid weakness in the absence of sensory abnormalities, diffuse areflexia, or bowel/bladder dysfunction.⁵⁰ Some of the patients experienced concurrent meningoencephalitis, and a few required mechanical ventilation.^{44,45}

Electrodiagnostic studies in patients with West Nile virus acute flaccid paralysis syndrome exhibit normal sensory potentials, and the absence of findings suggests segmental demyelination (e.g., motor conduction block, reduced conduction velocities, prolonged distal, and F-wave latencies), low-amplitude compound muscle action potentials in the affected regions, and marked denervation changes in the affected limbs and in corresponding paraspinal muscles on the needle electromyography. Corresponding magnetic resonance imaging (MRI) findings are sometimes observed and include an abnormal signal in the spinal cord on T2-weighted images^{47,48} and abnormal enhancement of the nerve roots and cauda equina.^{46,47} CSF analysis usually reveals mild pleocytosis with lymphocytic predominance and a mild to moderate protein elevation and normal glucose.⁵¹ Prognosis for the recovery of strength in these patients appears to be poor.⁵²

West Nile virus infection may be diagnosed by demonstrating West Nile virus RNA in the serum, CSF, or other tissues by reverse-transcriptase polymerase chain reaction, although this test is not highly sensitive.⁵³ More commonly, a diagnosis is made by the demonstration of West Nile virus IgM in CSF or serum by antibody-capture enzyme-linked immunosorbent assay (ELISA). When serum West Nile virus IgM is present, diagnosis is confirmed by a fourfold increase in West Nile virus IgG titers between acute and convalescent sera obtained 4 weeks apart. Positive IgM and IgG antibody titers should be confirmed by a plaque-reduction viral neutralization assay to exclude false-positive results related to other flaviviral infections, such as St. Louis encephalitis. Serology may not become positive until 8 days after symptom onset.³⁹

Particularly in the absence of a more typical encephalitic presentation of West Nile virus infection, a high index of clinical suspicion is needed to make a diagnosis of West Nile virus acute flaccid paralysis syndrome and to distinguish such cases from Guillain-Barré syndrome in patients presenting with acute weakness in the late summer or fall. Electrodiagnostic studies may help localize the pathology to the ventral horns of the spinal cord or ventral roots in West Nile virus cases and to exclude findings of segmental demyelination suggesting Guillain-Barré syndrome. CSF evaluation can help discriminate between the albuminocytologic dissociation of Guillain-Barré syndrome and the lymphocytic pleocytosis in a West Nile virus infection.

There is no specific treatment for West Nile virus. A multicenter study to evaluate the efficacy of Israeli IVIg (containing high levels of West Nile virus antibodies) in patients with West Nile virus meningoencephalitis or weakness was terminated early due to the lower-than-expected enrollment, expiration of the study product, and insufficient quantities of control IVIg.⁵⁴ Two candidate vaccines against West Nile virus are currently being evaluated.^{55,56}

Myasthenia Gravis

Myasthenia gravis is a consequence of the autoimmune attack on the acetylcholine receptor complex at the postsynaptic membrane of the neuromuscular junction. This process results in clinical weakness with a fluctuating pattern that is most marked after prolonged muscle exertion. Myasthenia gravis occurs at a higher rate in early adulthood in women, but in later life, the incidence rates for men and women become nearly equal. The reported prevalence is 14.2 cases per 100,000 population.⁵⁵ Myasthenia gravis typically involves ocular muscle weakness producing ptosis and diplopia, as well as bulbar muscle weakness resulting in dysphagia and dysarthria. A clinical diagnosis of myasthenia gravis may be supported by edrophonium testing, by electrophysiologic studies including repetitive nerve stimulation studies and single-fiber electromyography, and by acetylcholine receptor and muscle-specific receptor tyrosine kinase (MuSK) antibody testing.

Approximately 20% of patients with myasthenia gravis develop myasthenic crisis with respiratory failure requiring mechanical ventilation.⁵⁶ The most common precipitating factors include bronchopulmo-

BOX 55-2 Drugs That May Increase Weakness in Myasthenia Gravis

Neuromuscular blocking agents
Selected antibiotics
 Aminoglycosides, particularly gentamycin
 Macrolides, particularly erythromycin and azithromycin
Selected cardiovascular agents
 Beta-blockers
 Calcium channel blockers
 Procainamide
Quinidine
Quinine
Corticosteroids
Magnesium salts
 Antacids, laxatives, intravenous tocolytics
Iodinated contrast agents
D-Penicillamine

nary infections (29%) and aspiration (10%).⁵⁷ Other precipitating factors include sepsis, surgical procedures, rapid tapering of immune modulation, beginning treatment with corticosteroids, pregnancy, and exposure to drugs that may increase myasthenic weakness (Box 55-2).⁵⁸ Patients with myasthenia gravis are exceptionally sensitive to nondepolarizing neuromuscular blocking agents but resistant to depolarizing agents.⁵⁹ Thymomas are associated with more fulminant disease and identified in about one-third of patients in a myasthenic crisis.⁵⁷

Upper airway muscle weakness is a common mechanism leading to the myasthenic crisis.⁶⁰ Oropharyngeal and laryngeal muscle weakness may result in upper airway collapse with obstruction. Dysphagia further contributes to the obstruction and aspiration of secretions. Since a direct assessment of oropharyngeal muscle strength is impractical, a focused history and examination to assess surrogate muscles in the head and neck region are important. Findings of bulbar myasthenia associated with upper airway compromise include flaccid dysarthria with hypernasal, staccato, or hoarse speech, dysphagia (sometimes associated with nasal regurgitation), and chewing fatigue. Patients may exhibit facial weakness with difficulty holding air within the cheeks. Jaw closure is often weak and cannot be maintained against resistance. Patients with myasthenic tongue weakness may be unable to protrude the tongue into either cheek. Although neck flexors are often weaker, a dropped head syndrome due to neck extensor weakness may occur. Vocal cord abductor paralysis may produce laryngeal obstruction with associated stridor.^{61,62}

Patients with features of impending myasthenic crisis, including severe bulbar weakness, marginal vital capacity (less than 20 to 25 mL/kg), weak cough with difficulty clearing secretions from the airway, or paradoxical breathing while supine should be admitted to an ICU and made NPO to prevent aspiration.⁶³ Serial vital capacity and NIF measurements may be used to monitor ventilatory function in an impending myasthenic crisis. However, with significant bulbar weakness, these measurements are often inaccurate if the patient has difficulty sealing the lips around the spirometer mouthpiece or is unable to seal the nasopharynx. Vital capacity measurements may not reliably predict respiratory failure in myasthenia gravis, owing to the fluctuating nature of the myasthenic weakness.⁶⁴ The criteria for intubation and mechanical ventilation are similar to those for Guillain-Barré syndrome. If the upper airway is competent and there is no difficulty handling secretions or gross hypercapnia ($Paco_2 > 50$ mm Hg), intermittent nasal BiPAP may be a useful temporizing measure.⁴ Most patients who develop hypercapnia in myasthenic crisis require intubation, as do those who are becoming fatigued.

Plasma exchange is an effective short-term immunomodulating treatment for myasthenic crisis and surgical preparation in symptomatic myasthenic patients. Significant strength improvement in myasthenic crisis is well documented in several series,⁶⁵⁻⁶⁹ although there have been no controlled trials. We perform a series of five to six exchanges of 2 to 3 L every other day. The onset of improved strength is variable but occurs after two to three exchanges.

IVIg may represent an alternative short-term treatment for myasthenic exacerbations or crises in patients who are poor candidates for plasma exchange because of difficult vascular access or septicemia. Comparable efficacy for plasma exchange and IVIg was demonstrated in myasthenic exacerbations and crises in a relatively small randomized controlled trial of IVIg at 1.2 and 2 g/kg over 2 to 5 days.⁷⁰ However, in a retrospective multicenter study of myasthenic crisis, plasma exchange proved more effective than IVIg in the ability to extubate at 2 weeks and in the 1-month functional outcome.⁶⁹ Treatment failures to IVIg subsequently responding to plasma exchange have also been reported.⁷¹ Recent experience with preoperative IVIg for thymectomy in myasthenia gravis suggests that the time course of the maximal response may be considerably delayed in some patients.⁷²

Corticosteroids (e.g., prednisone, 1 mg/kg/day) are occasionally used in prolonged myasthenic crises that fail to respond to plasma exchange or IVIg. If begun early in the course of the myasthenic crisis, the transient increase in myasthenic weakness associated with initiating corticosteroids may prolong mechanical ventilation. When preceded by an unequivocal improvement in strength after plasma exchange or IVIg treatment, long-term treatment with corticosteroids may begin, with a reduced risk for corticosteroid-related exacerbations.

In the context of myasthenic crisis, excessive dosing of cholinesterase inhibitors may superimpose a cholinergic crisis due to depolarization blockade and result in increased weakness. Other symptoms of the cholinergic crisis include muscle fasciculations and prominent muscarinic symptoms including miosis, excessive lacrimation and salivation, abdominal cramping, nausea, vomiting, diarrhea, thick bronchial secretions, diaphoresis, and bradycardia. Cholinergic crisis is rare in contemporary series of myasthenic crisis,⁵⁷ and it is now common practice to avoid repeated dose escalations of cholinesterase inhibitors in an impending myasthenic crisis and to discontinue the use of cholinesterase inhibitors after intubation to reduce muscarinic complications. When there is a question of cholinergic excess contributing to respiratory insufficiency, it is prudent to discontinue all cholinesterase inhibitors, protect the airway, and support respiration as necessary.

Thymectomy may result in the long-term improvement of patients with a suspected thymoma or with a life expectancy of more than 10 years. However, a patient in acute respiratory failure is considered a poor operative risk, and thymectomy is delayed until the patient's condition has improved.⁷³ Post thymectomy pain control and ventilatory function may be improved by the postoperative administration of epidural morphine.⁷⁴

Neuromuscular Diseases Secondary to Critical Illness and Its Treatment

Critical Illness Polyneuropathy

Critical illness polyneuropathy is a widespread axonal peripheral neuropathy that develops in the context of multiple organ failure and sepsis.⁷⁵⁻⁷⁹ In a prospective series of 43 patients with sepsis and multi-organ failure, 70% developed electrophysiologic evidence of a sensorimotor axonal neuropathy, and 15 patients developed difficulty weaning from mechanical ventilation as a consequence of the neuropathy.⁸⁰ Critical illness polyneuropathy is possibly the most common neuromuscular cause of prolonged ventilator dependency in patients without prior known neuromuscular disease.⁸¹ Given the limitations to the detailed clinical motor and sensory examinations in the setting of critical illness, the clinical features of critical illness polyneuropathy (extremity muscle weakness and wasting, distal sensory loss, and paresthesias) may not be recognized. Deep tendon reflexes are reduced or absent in the setting of superimposed CNS insult with pyramidal tract dysfunction; however, deep tendon reflexes may be normal or increased.⁸²

Electrodiagnostic studies are important in establishing a diagnosis of critical illness polyneuropathy because the clinical findings may be unobtainable or indeterminate in this setting.⁸² Nerve conduction findings include normal or near-normal conduction velocity and latency values and significantly reduced compound muscle action potential

and sensory nerve action potential amplitudes. Needle electrode examination reveals denervation changes that are the most marked in the distal muscles, including fibrillation potentials, positive sharp waves, and reduced recruitment of motor unit potentials.⁸³ With recovery over time, the denervation potentials abate, and the motor unit potentials become polyphasic and enlarged. Peripheral nerve histopathology has revealed widespread primary axonal degeneration in distal motor and sensory fibers, and that skeletal muscle has exhibited fiber-type grouping.⁷⁹

Although the clinical history is usually adequate to distinguish between critical illness polyneuropathy and Guillain-Barré syndrome, the latter can develop in the context of recent surgery complicated by infection.⁸⁴ However, Guillain-Barré syndrome is commonly associated with facial and oropharyngeal weakness,⁸⁴ which is rarely seen in critical illness polyneuropathy.⁸⁵ Furthermore, dysautonomia and occasionally external ophthalmoplegia is also observed in Guillain-Barré syndrome but has virtually never been attributed to critical illness polyneuropathy.⁸⁵

Electrophysiologic findings are also helpful in distinguishing between these two disorders. Features of segmental demyelination may be observed in Guillain-Barré syndrome on nerve conduction studies (e.g., reduced conduction velocity, prolonged distal and F-wave latencies, conduction block, and temporal dispersion of compound muscle action potentials); these findings are not observed in critical illness polyneuropathy. Needle electromyographic findings may differ in that relatively less spontaneous activity is observed in clinically weak muscles within the first few days in patients with Guillain-Barré syndrome.⁸³ Although electrophysiologic studies are quite helpful in demonstrating the classic demyelinating form of Guillain-Barré syndrome, an electrophysiologic distinction between the axonal forms of Guillain-Barré syndrome and critical illness polyneuropathy may not be reliable. The mean CSF protein level in Guillain-Barré syndrome is significantly higher than in critical illness polyneuropathy, although there is overlap between these populations.⁸³ Peripheral nerve histopathology may also distinguish between these two groups because segmental demyelination and inflammatory changes may be observed in Guillain-Barré syndrome and are not observed in critical illness polyneuropathy.⁷⁹

Although the overall prognosis in critical illness polyneuropathy is dependent on recovery from the underlying critical illness, most patients who survive experience a functional recovery from the neuropathy within several months.⁷⁹ Critical illness polyneuropathy may prolong ventilator dependence, but it does not worsen the long-term prognosis.⁸² Proper positioning and padding are important to prevent compression neuropathies because the prognosis from superimposed compression neuropathies in the context of critical illness polyneuropathy is less favorable.⁸²

The pathophysiology of critical illness polyneuropathy is unknown. No clear metabolic, drug, nutritional, or toxic factors have been identified,⁷⁹ although the severity of critical illness polyneuropathy has been correlated with the amount of time in the ICU, the number of invasive procedures, increased glucose levels, a reduced albumin level,⁸⁰ and the severity of multiple organ failure.⁸⁶ Given the common antecedents of multiple organ failure and sepsis in which release of cytokines occurs, increased microvascular permeability has been postulated to produce axonal hypoxia and degeneration as a consequence of endoneurial edema.⁸⁷

Prolonged Effects of Neuromuscular Blocking Agents

A prolonged neuromuscular blockade may occur with most depolarizing and nondepolarizing agents, particularly when the hepatic or renal function is impaired.⁸⁸ In one study, the administration of vecuronium for 2 or more consecutive days resulted in prolonged neuromuscular blockade and paralysis lasting from 6 hours to 7 days.⁸⁹ Although vecuronium is hepatically metabolized, patients with renal failure were susceptible to prolonged effects due to delayed excretion of the active 3-desacetyl metabolite. Acidosis and elevated serum magnesium levels were also associated with prolonged paralytic effects of

vecuronium. A peripheral nerve stimulator may be used to monitor muscle twitch responses to a train-of-four stimulus during the use of neuromuscular blocking agents. Drug dosage should be titrated to preserve one or two twitches to avoid overdosing. Two- to 3-Hz repetitive nerve stimulation studies may also be used to confirm neuromuscular blockade when it is suspected. Since atracurium and cisatracurium do not require organ metabolism for clearance, they are rarely associated with this problem.

Acute Quadriplegic Myopathy

The syndrome known as *acute quadriplegic myopathy*⁹⁰ or *acute myopathy of intensive care*⁹¹ was originally described in 1977 by a young woman who developed severe myopathy after treatment of status asthmaticus with high doses of corticosteroids and pancuronium.⁹² Subsequently, there have been many citations of an acute myopathy developing in critically ill patients without preexisting neuromuscular disease. Acute quadriplegic myopathy has developed most frequently in the setting of severe pulmonary disorders in which neuromuscular blockade is used to facilitate mechanical ventilation, and high doses of corticosteroids are concurrently administered. In most reported cases, myopathy developed when nondepolarizing neuromuscular blocking agents were used for more than 2 days.⁹⁰⁻¹⁰⁰ The development of acute necrotizing myopathy with myosin loss also occurs in patients receiving high doses of corticosteroids and hypnotic doses of propofol and benzodiazepines to induce paralysis.¹⁰¹ This observation highlights the significance of high-dose corticosteroid exposure in the development of this syndrome and suggests that the paralyzed muscles may be susceptible to the toxic effects of corticosteroids. The mechanism of this myosin abnormality appears to lie at the level of transcriptional regulation of protein synthesis.¹⁰² The occurrence of acute quadriplegic myopathy after organ transplantation may be caused by the use of high doses of corticosteroids to prevent graft rejection, along with perioperative exposure to neuromuscular blocking agents.¹⁰³ Although most cases of acute quadriplegic myopathy have been associated with critical illness and high doses of corticosteroids and paralytic agents, acute quadriplegic myopathy has developed after isolated corticosteroid exposure,^{90,104-107} isolated nondepolarizing neuromuscular blocking agent use,^{100,104,108} or neither.¹⁰⁹ Factors that may impair neuromuscular transmission (e.g., hypermagnesemia and aminoglycoside exposure), factors that may slow the elimination of nondepolarizing neuromuscular blocking agents (e.g., hepatic or renal failure), and factors associated with critical illness (e.g., sepsis and acidosis) are also associated with acute quadriplegic myopathy.⁹³

In typical cases, a diffuse flaccid quadriparesis with the involvement of respiratory muscles and muscle wasting evolves after several days of induced paralysis. External ophthalmoparesis has rarely been noted.^{110,112} Sensation remains intact, but deep tendon reflexes are reduced or absent. The creatine kinase level is commonly elevated, but this may not be observed if creatine kinase is measured well after the myopathy has developed. Although the paralysis may be quite severe and necessitate or prolong mechanical ventilation, the prognosis for the myopathy is good, with functional recovery over several weeks to months.⁹⁵ Electromyographic findings include reduced amplitude of compound motor action potentials with normal sensory nerve action potentials and normal nerve conduction velocities. M-wave amplitude improvement accompanies clinical recovery.¹⁰⁰ Repetitive nerve stimulation studies may yield decremental responses, while the residual effects of nondepolarizing neuromuscular blocking agents or their active metabolites persist.^{93,100} Needle electromyography often reveals small, low-amplitude, polyphasic motor unit potentials exhibiting early recruitment, along with positive sharp waves and fibrillation potentials. A spectrum of muscle histologic changes may be observed, ranging from type II fiber atrophy and the loss of adenosine triphosphatase (ATPase) reactivity in atrophic fibers to fiber necrosis in severe cases. However, the distinctive findings in most cases is an extensive loss of thick filaments corresponding to myosin loss.^{90,94,99,104,109} This finding may be demonstrated by immunohistochemical staining or electron microscopy. The increased expression of steroid receptors in

denervated and immobilized muscle¹¹¹ may render these muscles susceptible to toxic catabolic effects of steroids.^{90,113} Given the growing recognition of acute quadriplegic myopathy, the use of high doses of corticosteroids should be avoided if possible when neuromuscular blockade or induced paralysis is required.

However, in a recent Cochrane review of interventions for preventing critical illness polyneuropathy and critical illness myopathy,¹¹⁴ a randomized controlled trial of 180 patients with acute respiratory distress syndrome comparing corticosteroids to placebo that found no effect of treatment on critical illness polyneuropathy/myopathy¹¹⁵ was cited as moderate quality evidence. Additional results from the review found moderate evidence for intensive insulin therapy in reducing polyneuropathy/myopathy at the expense of increased hypoglycemia^{116,117} and for a potential benefit for early rehabilitation.¹¹⁸ Larger randomized controlled trials of early rehabilitation and electrical muscle stimulation is needed to explore the value of these therapies.

KEY POINTS

1. Respiratory dysfunction due to neuromuscular disease typically presents with a combination of upper airway dysfunction and diminished tidal volume (VT).
2. Along with vital capacity, trended measurement of the maximum inspiratory pressure (PImax or negative inspiratory force [NIF]) is a useful index of ventilatory capacity. Inability to maintain a PImax greater than 20 to 25 cm H₂O usually indicates a need for mechanical ventilatory assistance.
3. Autonomic failure and pulmonary embolism are now the major causes of mortality in Guillain-Barré syndrome.
4. Evidence-based guidelines for Guillain-Barré syndrome immunotherapy have been published by the Quality Standards Subcommittee of the American Academy of Neurology. Plasma exchange is recommended for adult patients who cannot walk within 4 weeks of symptom onset. Intravenous immune globulin (IVIg) is recommended in these patients within 2 or possibly 4 weeks of symptom onset. Plasma exchange and IVIg are considered equivalent in efficacy, and no additional benefit is conferred by combining these treatments. In light of the therapeutic equivalence, the decision whether to employ plasma exchange or IVIg in treating acute Guillain-Barré syndrome may be determined by resource availability and by avoiding potential side effects related to a patient's medical comorbidities.
5. In the initial North American outbreak of West Nile virus, about 10% of infected patients experienced flaccid weakness with clinical features resembling Guillain-Barré syndrome.
6. Approximately 20% of patients with myasthenia gravis develop myasthenic crisis with respiratory failure requiring mechanical ventilation.
7. Critical illness polyneuropathy is a widespread, axonal peripheral neuropathy that develops in the context of multiple organ failure and sepsis. Critical illness polyneuropathy is possibly the most common neuromuscular cause of prolonged ventilator dependency in patients without prior known the neuromuscular disease.
8. Acute quadriplegic myopathy has developed most frequently in the setting of severe pulmonary disorders in which neuromuscular blockade is used to facilitate mechanical ventilation, and high-dose corticosteroids are concurrently administered.

An estimated 3.2 million people are living with long-term disability related to traumatic brain injury (TBI).¹ In addition to the personal toll, the direct and indirect costs of these disabilities are estimated to exceed \$60 billion annually.² Americans sustain an estimated 1.6 million TBIs each year. Approximately 290,000 require hospitalization, and 51,000 die of their injuries.³ TBI is the leading cause of morbidity and mortality for Americans between the ages of 1 and 45 years. Teenagers and the elderly are most at risk, although the primary causes vary demographically. Motor vehicle crashes are the main cause of head injuries in those 5 to 64 years old, whereas falls are most common in the pediatric population and people aged 65 years and older.⁴ The primary cause of penetrating head injury is gunshot wounds. Males have twice the risk of sustaining TBI as females across all age groups and are three times more likely to die as a result of their injury.

■ PATHOPHYSIOLOGY

Trauma to the head causes primary injury such as skull fracture, cerebral contusion, and hemorrhage that is a direct physical consequence of the impact. Hours or days after the traumatic incident, secondary injury occurs and may be a major determinant of the patient's ultimate neurologic outcome. Injury to the brain is caused by external forces to the head that strain the tissue beyond its structural tolerance.⁵ These forces can be classified as contact or inertial.⁶ Contact forces typically produce focal injuries such as skull fractures, contusions, and epidural or subdural hematomas. Inertial forces result from the brain undergoing acceleration or deceleration (translational, rotational, or both) and can occur without head impact.

Skull fracture results from a contact force to the head that is usually severe enough to cause at least a brief loss of consciousness. Linear fractures are the most common type of skull fracture and typically occur over the lateral convexities of the skull. A depressed skull fracture, in which skull fragments are pushed into the cranial vault, usually results from blunt force by an object with a relatively small surface area, such as a hammer (Fig. 56-1). Basilar skull fractures are most common in the anterior skull base and often involve the cribriform plate, disrupting the olfactory nerves (Fig. 56-2). Posterior basilar skull fractures may extend through the petrous bone and internal auditory canal, thereby damaging the acoustic and facial nerves.

Skull fractures per se are less detrimental than the associated damage to underlying tissues or vessels. For example, linear skull fractures that involve the squamous portion of the temporal bone are frequently accompanied by a tear of the middle meningeal artery, causing an epidural hematoma. They can also cause facial nerve injury, exhibited as facial asymmetry that can present immediately or in a delayed fashion. Depressed skull fractures are often associated with contusions of the underlying brain tissue, and a scalp laceration overlying a depressed skull fragment can contaminate the fragment with bacteria from the scalp and hair. With a basilar skull fracture, the dura underlying the fracture is often disrupted, resulting in a cerebrospinal fluid (CSF) fistula and leakage of CSF from the nose or ear. Such fistulas allow bacteria to enter the intracranial space from the normally colonized nose, paranasal sinuses, or external auditory canal.

Common posttraumatic intracranial lesions include hemorrhage (epidural, subdural, and intraparenchymal), contusion, and diffuse

brain injury. Subdural hematomas are seen in 20% to 25% of all comatose victims of TBI (Fig. 56-3). They develop between the surface of the brain and the inner surface of the dura and are believed to result from the tearing of bridging veins over the cortical surface or from disruption of major venous sinuses or their tributaries. The hematoma typically spreads over most of the cerebral convexity; the dural reflections of the falx cerebri prevent expansion to the contralateral hemisphere. Swelling of the cerebral hemisphere is common in those with subdural hematomas, given the associated damage to underlying brain tissue. Underlying cerebral contusions were found in 67% of patients with subdural hematomas in one series.⁷ Subdural hematomas are classified as acute, subacute, or chronic, each having a characteristic appearance on computed tomography (CT): acute hematomas are bright white, subacute lesions are isodense with brain tissue and are therefore often overlooked, and chronic hematomas are hypodense relative to the brain.

Epidural hematomas develop between the inner table of the skull and the dura, usually when the middle meningeal artery or one of its branches is torn by a skull fracture. They occur in 8% to 10% of those rendered comatose by TBI.⁸ The majority of epidural hematomas are located in the temporal or parietal regions, but they can also occur over the frontal or occipital lobes and (rarely) in the posterior fossa. They appear as hyperdense mass lesions on CT. Unlike subdural hematomas, their spread is limited by the suture lines of the skull, where the dura is very adherent (Fig. 56-4). Epidural hematomas are uncommon in infants and toddlers, presumably because their skulls are more deformable and less likely to fracture, and in TBI victims older than 60 years, because the dura is extremely adherent to the skull.

An intraparenchymal hematoma is a hemorrhage within the brain substance that occurs after TBI. It is usually associated with contusions of the surrounding tissue. Duret hemorrhage, or hemorrhage into the base of the pons or midbrain, is thought to result from disruption of the perforating arteries at the time of uncus herniation. Such brainstem hemorrhage almost always leads to death or minimally responsive survival.

Traumatic subarachnoid hemorrhage often results from tearing of the corticomeningeal vessels. Though common after severe TBI, subarachnoid hemorrhage does not produce a hematoma or mass effect.⁹ However, it may be associated with an increased risk for posttraumatic vasospasm, which may adversely affect clinical outcome.¹⁰

Contusions are heterogeneous lesions comprising punctate hemorrhage, edema, and necrosis and are often associated with other intracranial lesions. One or more contusions occur in 20% to 25% of patients with severe TBI. Because they evolve over time, contusions may not be evident on the initial CT scan or may appear as small areas of punctate hyperdensities (hemorrhages) with surrounding hypodensity (edema) (Fig. 56-5). Local neuronal damage and hemorrhage lead to edema that may expand over the next 24 to 48 hours. With time, contusions may coalesce and look more like intracerebral hematomas. Depending on their size and location, they may cause significant mass effect, resulting in midline shift, subfalcine herniation, or transtentorial herniation. Contusions are most common in the inferior frontal cortex and the anterior temporal lobes,¹⁰ where the surface of the inner table of the skull is very irregular. Direct blunt-force trauma to the head can produce a contusion in the tissue underlying the point of impact (coup contusion). If the head was in motion upon collision with a rigid

FIGURE 56-1 ■ Right frontal depressed skull fracture caused by an assault with a hammer (axial computed tomography scan, bone window).

FIGURE 56-3 ■ Acute subdural hematomas (SDH) typically spread over entire surface of the hemisphere. Occasionally, mixed-density SDH is seen, indicative of injuries occurring at different times.

FIGURE 56-2 ■ Basilar skull fractures through the anterior skull base typically cause rhinorrhea and tears in adjacent dura. Computed tomography (CT) scans through the base of the skull may not show the fracture itself but often show fluid in the sphenoid sinus or other paranasal sinuses (axial CT scan, bone window).

FIGURE 56-4 ■ Epidural hematomas have a lens shape and smooth inner border because they strip the dura from the inner table of the skull as they enlarge (axial computed tomography scan).

surface, a contusion may occur in the brain contralateral to the point of impact (contrecoup contusion).

Diffuse axonal injury refers to lacerations or punctate contusions at the interface between the gray and white matter. Such punctate contusions are thought to result from the disparate densities of the gray and white matter and the consequent difference in centripetal force associated with a rotational vector of injury.¹¹ Diffuse axonal injury was once thought to result solely from mechanical disruption at the time of impact; however, more recent research has identified cases in which the histologic footprints of diffuse axonal injury, such as fragmentation of axons and axonal swelling, do not appear until 24 to 48 hours after the incident, suggesting that some cases are a secondary manifestation

of trauma.^{12,13} Diffuse axonal injury is present in almost half of all patients with severe TBI and in a third of those who die, and it is a common cause of persistent vegetative or minimally conscious state.¹⁴

Posttraumatic intracranial lesions cause neurologic dysfunction via direct and in some cases indirect mechanisms. By destroying brain tissue, contusions and intraparenchymal hemorrhage cause deficits directly related to the function of the damaged tissue. Uncal herniation is also an important mechanism of temporary or permanent neurologic deficits.^{15,16} Semirigid dural reflections divide the intracranial contents into compartments. The tentorium cerebelli separates the anterior and middle cranial fossae from the posterior cranial fossa. The brainstem, specifically the midbrain, traverses an opening, the tentorial foramen, in the anterior central portion of this partition. The medial portion of the temporal lobe, the uncus, lies on both sides of the

FIGURE 56-5 ■ Contusions are most common in the inferior temporal and frontal lobes. In the first few hours after injury, they appear only as areas of hemorrhage mixed with edematous brain. Within 24 to 48 hours after injury, further hemorrhage may occur, causing significant enlargement of the contusion and hematoma (axial computed tomography scan).

tentorial foramen. Hematomas and contusions located over the lateral surfaces of the brain can depress the brain medially and displace the medial portion of the temporal lobe (uncus) into the tentorial foramen (i.e., uncal herniation). Such displacement compresses the midbrain, which contains neurons that are part of the reticular activating system. Midbrain compression due to uncal herniation damages the reticular activating system, causing loss of consciousness; stretches the third cranial nerve and its associated parasympathetic fibers, causing pupil dilatation and loss of the light reflex; and injures the pyramidal fibers in the crus cerebri, causing abnormal posturing responses in the contralateral arm and leg.

Intracranial hypertension is a major cause of posttraumatic neurologic morbidity and mortality.¹⁷ The intracranial pressure (ICP) is defined by the volume of CSF, blood, and brain tissue in the cranial vault. The volume of these components is dynamic, and the brain can accommodate moderate changes in any of the three. Thus, the intracranial volume can gain 100 to 150 mL, equivalent to a moderate-sized subdural hematoma, without the ICP increasing significantly. When these buffering mechanisms have been exhausted, however, even a small increase in the size of a hematoma will cause a rapid rise in ICP. If appropriate treatment is delayed, the ICP may approach the mean arterial pressure (MAP), causing a hydrostatic block of blood flow to the brain and brain death.

■ PREHOSPITAL CARE

The acutely injured brain is vulnerable to further damage from systemic hypotension, cerebral hypoperfusion, hypercarbia, hypoxemia, and elevated ICP. Preventing these physiologic insults is crucial to limiting secondary brain injury. Care of the TBI victim always should begin with evaluating and securing a patent airway and restoring normal breathing and circulation, as such treatment has been shown to reduce mortality after severe TBI.^{18,19}

The airway is usually most easily and safely secured by orotracheal intubation. Patients with severe maxillofacial trauma may require nasotracheal intubation, but this is less desirable because it is a relatively blind procedure. A third alternative for securing the airway is the laryngeal mask airway, an easily learned and rapidly applied device

BOX 56-1

Recommended Rapid-Sequence Induction for Severely Head-Injured Patients

1. Preoxygenation
100% oxygen for 5 min or four vital capacity breaths
2. Pretreatment
Fentanyl (3 to 5 µg/kg IV)
3. Wait 2 to 3 min if possible
Continue preoxygenation
4. Neuromuscular blockade and sedation
Succinylcholine (1.5 mg/kg IV) or rocuronium (1.0 mg/kg IV)
5. Intubation with in-line cervical spine immobilization
Positive-pressure ventilation and possibly maintaining neuromuscular blockade with vecuronium and additional analgesia and sedation if prolonged transport time is anticipated

that has undergone successful field trials.²⁰ A surgical airway (cricothyroidotomy) should be performed only after other attempts to secure an airway have failed. Rapid-sequence intubation is recommended to prevent transient hypertension, tachycardia, increased ICP, and agitation that can interfere with the procedure. **Box 56-1** shows a recommended rapid-sequence intubation pathway.

Supplemental oxygen should be provided before and immediately after intubation. Ventilatory rates of 10 to 12 breaths per minute for adults, 20 breaths per minute for children, and 25 breaths per minute for infants should supply adequate oxygenation. Therapeutic hyperventilation is inadvisable unless neurologic deterioration is clearly evident during evaluation and transport. Aggressive hyperventilation can cause cerebral vasoconstriction, reducing already low cerebral blood flow (CBF) and potentially causing or exacerbating cerebral ischemia.²¹

Rapid fluid resuscitation and restoration of a normal BP are critical in the prehospital setting, because hypotension has been associated with doubling of the mortality rate after severe TBI.²² The most likely cause of hypotension is hemorrhage, usually in the abdomen or chest; therefore, hypovolemia should be assumed. Lactated Ringer's or normal saline solutions should be infused through a large-bore IV catheter as quickly as possible until normotension is achieved.

In all cases of severe TBI, defined as a Glasgow Coma Scale (GCS) score of 3 to 8 and an inability to follow commands, patients should be treated as if they have a spinal fracture until an adequate examination of the spine proves otherwise. Among those who survive long enough to reach the emergency department, the likelihood of a cervical spine fracture is 2% to 7%. More troubling, however, is that an estimated 10% to 25% of all posttraumatic spinal cord injuries are iatrogenic, occurring during transport to the hospital.²³ After respiratory and hemodynamic stabilization, the patient should be placed in a neutral position on a flat, hard surface. A rigid cervical spine collar should be placed, followed by immobilization on a long spine board.

■ EMERGENCY DEPARTMENT CARE

Upon arrival at the trauma center, the emergency medical personnel should concisely report their prehospital assessment and management, including mechanism of injury, stabilizing maneuvers, medications given, initial vital signs, GCS score, and hemodynamic stability during transport.¹⁸ A thorough physical and radiographic examination to identify all life-threatening injuries should then be performed. Most trauma centers follow the Advanced Trauma Life Support protocol, a comprehensive routine that has proved successful in quickly detecting all major injuries.²⁴ Any life-threatening injuries such as overt hemorrhage, tension pneumothorax, or cardiac tamponade should be treated immediately upon discovery. A brief neurologic examination is performed, including assessment of the GCS score (**Table 56-1**), pupillary size and reaction to light, and symmetry and extent of extremity movements. The head is palpated to detect fractures, lacerations, or

TABLE 56-1 Glasgow Coma Scale⁵⁹

| RESPONSE | POINTS |
|--|--------|
| SPEECH | |
| Alert, oriented, and conversant | 5 |
| Confused, disoriented, but conversant | 4 |

| Flexor posturing with central pain | 3 |
| Extensor posturing with central pain | 2 |
| No response to painful stimulus | 1 |

Data from Teasdale G, Jennett B. Assessment of coma and impaired consciousness: a practical scale. *Lancet* 1974;2:81–84.

penetrating wounds, and lacerations are probed gently to ascertain the presence of a depressed skull fracture or foreign body. Large lacerations are compressed with pressure dressings or temporarily sutured to prevent further hemorrhage.

Coagulopathy resulting from TBI is thought to occur when hypoperfusion causes activation of the protein C pathway, thereby inducing alterations in the clotting cascade.²⁵ It is also commonly seen as a result of therapeutic anticoagulation with warfarin and novel anticoagulants, especially in the geriatric population. Fresh frozen plasma and cryoprecipitate can be used to correct the INR to 1.3 or less. Prothrombin complex concentrates (PCCs) and recombinant factor VIIa have been shown to decrease blood product requirements and costs associated with correction of coagulopathy.^{26–28}

After all life-threatening injuries have been identified and stabilized, the immediate concern is whether the patient requires a craniotomy to evacuate an intracranial mass lesion. A CT scan of the head should be performed at intervals of 5 mm or less from the C2 vertebra to the vertex. If no surgical intracranial mass lesion is evident on the scan of the head, CT scans of the cervical spine, chest, and abdomen can be performed to detect occult injuries in these areas. If a surgical mass lesion is seen on the head CT scan, it should be evacuated immediately, postponing any other imaging studies. Diagnostic peritoneal lavage may be performed during the craniotomy to detect abdominal bleeding if needed.

DEFINITIVE TREATMENT

Critical to determining the initial severity of the brain injury and appropriate treatment are CT findings combined with a reliable exam of neurologic function.²⁹ In the case of an acute subdural hematoma, for example, a patient with a moderate-sized lesion who has normal pupil size and reactivity and is able to follow commands might safely be treated nonoperatively.⁹ Conversely, surgery is unlikely to benefit an elderly patient with fixed and dilated pupils and a GCS score of 3 or 4, regardless of the CT findings.³⁰ Other determining factors include size and location of the hematoma, presence and extent of an underlying contusion or brain swelling, and results of the neurologic examination. Neurologic deterioration, particularly a decline in mental status, suggests enlargement of the hematoma, and a new CT scan should be obtained promptly. Hematomas less than 10-mm thick that cause a midline shift of less than 5 mm can usually be observed, especially if they do not involve the middle cranial fossa.³¹ If nonoperative management is chosen for an intracranial hematoma, the patient should be

FIGURE 56-6 ■ Temporal lobe contusions must be monitored closely because even a slight enlargement can cause uncal herniation, often without an increase in intracranial pressure (ICP) (axial computed tomography scan).

monitored with frequent neurologic assessments in the intensive care unit (ICU).

The classic presentation of a patient with an epidural hematoma is a period of unconsciousness immediately after impact to the head, followed by a so-called lucid interval in which consciousness returns for a few minutes to an hour or more before the patient lapses into a coma. This lucid interval actually occurs in less than a third of patients with epidural hematomas, however; most either remain conscious after the injury (smaller clots) or remain comatose.

A hematoma that compresses the temporal lobe is particularly ominous and can rapidly cause uncal herniation with minimal enlargement. Such lesions warrant a lower threshold for evacuation compared with hematomas in other locations. Small hemorrhages managed nonoperatively should be monitored with frequent CT scans during the first several days after injury. Enlarging middle fossa hematomas, even those large enough to cause herniation, do not always cause an increase in the ICP; therefore, ICP monitoring should not be relied on to follow their status.

The initial signs and symptoms of contusions vary greatly depending on their size and location and the presence of other associated lesions. A small contusion may cause only a headache or no symptoms at all. If located in an eloquent area of the brain, such as the speech or motor areas, it may cause focal neurologic symptoms. Larger contusions, especially those involving the frontal or temporal lobes, typically cause elevated ICP and coma. The contusion should be followed closely with serial CT scans because there is a 20% to 30% risk that the contusion will enlarge during the next 24 to 48 hours. The ICP should be monitored if the patient cannot follow commands. As with hematomas in the middle cranial fossa, contusions of the temporal lobes should be closely watched with CT scans. A temporal contusion can enlarge to the point of uncal herniation without a significant rise in ICP, so the threshold for evacuation of these lesions should be low (Fig. 56-6). Unilateral frontal or temporal lobectomies are usually well tolerated and do not cause measurable neurologic deficits, while allowing space for further brain swelling.³²

In the ICU, the primary goal is to prevent cerebral ischemia and thereby limit secondary brain injury. The most common preventable causes of cerebral ischemia are hypotension, hypoxemia, and intracranial hypertension. Comprehensive physiologic monitoring should be performed so that these physiologic insults can be detected and treated promptly.

■ PHYSIOLOGIC MONITORING

Continual monitoring of the end-tidal partial pressure of carbon dioxide (PCO_2) and frequent analyses of arterial blood gases enable the early detection of deteriorating ventilatory status, which should prompt appropriate ventilator adjustments. Oxygen saturation should also be monitored continually with pulse oximetry. BP monitoring is best accomplished with an indwelling arterial catheter coupled to a pressure transducer. Central venous pressure (CVP) monitoring should be considered for patients with severe TBI, particularly those with significant non-CNS injuries. In elderly patients or those with severe pulmonary contusions, intravascular volume may be more accurately assessed by pulmonary artery catheterization with a Swan-Ganz catheter or the less invasive, Flo-Trac Vigileo. Monitoring urine output with an indwelling Foley catheter is essential for determining the patient's fluid status.

Continuous ICP monitoring is essential for all patients who have severe TBI and abnormal CT findings, because intracranial hypertension develops in 53% to 63% of such patients.^{33,34} ICP monitoring is also recommended for comatose patients who are older than 40 years and have unilateral or bilateral motor posturing or a systolic blood pressure (SBP) less than 90 mm Hg, even if no abnormalities are seen on the initial CT scan. The gold standard for ICP monitors is the ventricular catheter coupled to an external strain-gauge transducer.^{35,36} It is accurate, reliable, and less expensive than newer self-contained pressure-sensing devices. In addition, ventricular pressure is considered more reflective of global ICP than is subdural, subarachnoid, or epidural pressure. Other advantages of the ventriculostomy method of ICP monitoring are that the system can be re-zeroed after insertion—not possible with most of the newer self-contained devices—and CSF can be withdrawn to treat intracranial hypertension. The overall complication rate for ventricular ICP monitoring is 7.7% (infection, 6.3%; hemorrhage, 1.4%).³⁷ Some studies indicate that the infection rate increases significantly when a catheter remains in place for more than 5 days,³⁸ although this is less likely with the use of antibiotic-impregnated ventricular catheters.

Alternatives to the ventriculostomy technique have been developed that provide relatively accurate measurements of global ICP, are easier to insert, and may cause fewer complications. They include devices that contain a pressure-sensing transducer (either strain-gauge or fiber-optic technology) within the tip of the catheter.³⁴ These pressure sensors provide reliable ICP measurements even if they are inserted into the white matter and are often used when a ventricular catheter is difficult to insert because of small or collapsed ventricles. The primary disadvantage is that CSF drainage is not possible. In addition, these devices can be calibrated only once, before insertion, and with some of them, measurement drift is as much as 1 to 2 mm Hg per day. Measurement of the ICP can then be used to calculate the cerebral perfusion pressure (CPP), defined as the difference between MAP and ICP, which describes actual cerebral perfusion. The current recommendation is to maintain a CPP above 50 mm Hg.³⁹

Devices that monitor the oxygen partial pressure of oxygen (Pbto_2) of brain tissue can be used to determine whether cerebral oxygenation is adequate. These monitors continually measure the tissue Pbto_2 in the small region of brain into which they are inserted. Studies suggest that mortality may be decreased in those undergoing oxygen directed therapy.⁴⁰⁻⁴² Although no methods are available for continuously monitoring global CBF, transcranial Doppler insonation of the middle cerebral arteries can provide indirect information. Positron emission tomography (PET) or CBF measurements with xenon, either as a radiolabeled agent or as a CT contrast medium, can provide periodic snapshots of the blood flow.

■ MEDICAL TREATMENT

Hypoxemia is best avoided with the use of tracheal intubation and mechanical ventilation. The fraction of inspired oxygen should be titrated to provide an arterial Po_2 of 100 mm Hg.⁴³ Maintaining an arterial PCO_2 of approximately 35 mm Hg is advised to avoid the

cerebral vasoconstriction associated with aggressive hyperventilation. A form of acute respiratory distress syndrome (ARDS) can develop in some patients. In such cases, adequate oxygenation requires the use of positive end-expiratory pressure (PEEP). Concern has been raised that the use of PEEP in patients with TBI may increase the ICP. However, clinical studies have shown that in the presence of ARDS, up to 14 to 15 cm H_2O of PEEP can be used without measurable changes in ICP.

Hypotension, defined as a SBP of less than 90 mm Hg, should be treated aggressively. Normovolemia should be restored by infusing isotonic saline as needed to achieve a central venous pressure of 7 to 12 cm H_2O .⁴³ Hypotonic intravenous solutions can exacerbate cerebral edema and should be avoided. If the patient is anemic, packed red blood cells should be transfused to restore the hematocrit to at least 30%. If hypotension is refractory to volume resuscitation, the patient should be started on vasopressors, with the dose titrated to raise the SBP above 90 mm Hg. Norepinephrine has been shown to be most efficacious at maintaining MAP and CPP without deleteriously affecting ICP.⁴⁴

Intracranial hypertension is defined as sustained ICP greater than 20 mm Hg. Several clinical studies have found that mortality and morbidity increase significantly when the ICP persistently remains above this threshold.⁴⁵ Based on this association and the widely accepted premise that elevated ICP can compromise cerebral perfusion and cause ischemia, the aggressive treatment of intracranial hypertension is almost uniformly endorsed. Seizures, hypercapnia, fever, jugular venous outflow obstruction (e.g., poorly fitting cervical collars), and agitation can cause or exacerbate intracranial hypertension. A stepwise approach for ICP treatment is usually followed, with the least toxic therapies used first and more toxic therapies added only if the initial treatment is unsuccessful. Sedation and neuromuscular blockade are often an effective first treatment, particularly if the patient is agitated or posturing.⁴⁶ Narcotics (e.g., morphine, fentanyl), short-acting benzodiazepines (e.g., midazolam), or hypnotic agents such as propofol can be used for sedation, and vecuronium bromide as the paralytic agent. Narcotic-induced hypotension can be averted by using relatively low doses and ensuring the patient is normovolemic before treatment. Because the ability to obtain an accurate GCS score is lost during this treatment, the pupil status, ICP, and CT scans must be closely monitored.

If intracranial hypertension is refractory to sedation and neuromuscular blockade, intermittent ventricular CSF drainage is used. Intermittent rather than continuous drainage enables reliable measurement of the ICP. If these measures fail to reduce the ICP, a bolus administration of mannitol (0.25 to 1 g/kg every 3 to 4 hours as needed) or hypertonic saline is recommended.⁴⁷⁻⁴⁹ Mannitol exerts its effect through osmotic diuresis, lowering the ICP and increasing the CPP by expanding the blood volume, reducing the blood viscosity, and increasing CBF and oxygen delivery to the tissues within a few minutes of infusion. Its duration of effect averages 3 to 5 hours. Continuous infusion is less desirable than bolus infusion, because the former is more likely to lead to extravasation of the drug into brain tissue, causing a reverse osmotic gradient and increased edema and ICP. The intravascular volume should also be closely monitored to prevent dehydration. Hypertonic saline appears to create osmotic mobilization of water across the blood-brain barrier. Concentrations ranging from 3% to 23.4% have been used to decrease ICP.⁴⁸ The serum osmolality and sodium level should be monitored frequently during the use of osmotherapy. The drugs should be discontinued if the serum sodium level exceeds 160 mg/dL or the osmolality exceeds 320 mOsm in order to minimize the risk of acute kidney injury.⁵⁰

If despite these measures the ICP remains above 20 mm Hg, the ventilatory rate can be adjusted to reduce the arterial PCO_2 to 30 mm Hg.²¹ Hyperventilation should be used cautiously during the first 24 to 48 hours after injury, because it will cause cerebral vasoconstriction at a time when CBF is already critically reduced. Evidence also suggests that even brief periods of hyperventilation can lead to secondary brain injury by causing an increase in extracellular lactate and glutamate levels.⁵¹ Prophylactic hyperventilation is always

contraindicated in the absence of elevated ICP.⁵² If hyperventilation is used, the brain tissue P_{bO_2} or jugular venous oxygen saturation should be monitored to detect any cerebral ischemia that the treatment might cause. The risk of tissue ischemia and poor outcome may increase if the brain tissue P_{bO_2} falls below 10 mm Hg.⁴²

If intracranial hypertension persists despite all these treatments, particularly if the ICP rises rapidly or if the patient's initial CT scan showed a small contusion or hematoma, another CT scan should be obtained immediately to determine whether there is a new mass lesion or a preexisting lesion has enlarged. Even if the lesion has enlarged only slightly, an emergent craniotomy and evacuation of the contusion or hematoma may be the best way to reduce the ICP quickly and effectively.

In the absence of new or expanding mass lesions, high-dose barbiturates can be considered in patients with salvageable neurologic exams. Pentobarbital is the most commonly used drug for this purpose and is administered as an IV loading dose of 10 to 15 mg/kg over 1 to 2 hours, followed by a maintenance infusion of 1 to 2 mg/kg per hour. Continuous electroencephalographic monitoring is recommended while increasing the dose until a burst suppression pattern is observed. Hypotension, the most common adverse effect of barbiturates, can usually be averted by ensuring a normal intravascular volume before administering the drug.

Therapeutic moderate hypothermia has been used in several clinical trials over the past decade. The body temperature is lowered to 32°C to 33°C as soon as possible after injury and kept at that temperature for 24 to 48 hours using surface cooling techniques. Although some clinical trials have not found that this treatment improves neurologic outcome compared with normothermia, they have consistently shown that hypothermia significantly reduces ICP.^{53,54}

The use of decompressive craniectomies, such as large lateral or bifrontal bone flaps, with or without a generous temporal or frontal lobectomy can be considered for a small subset of patients. Two studies report good outcomes in 56% to 58% of patients whose refractory intracranial hypertension was treated with decompressive craniectomy as a last resort,^{55,56} and another study suggested that decompressive temporal lobectomy, when performed soon after injury, improves the outcome for young patients.^{32,57} However, others found that decompressive craniectomy does not improve ICP, CPP, or mortality rates.⁵⁸ Because age has such a profound impact on the likelihood of a meaningful recovery, these second tier therapies are recommended only for patients who are younger than 40 years old.

Failure to control intracranial hypertension may result in brain death, the irreversible cessation of cerebral function. Clinically, this is manifested by loss of motor function and brainstem reflexes including pupillary response, corneal reflex, cough reflex, and oculovestibular reflexes.⁵⁹ Once these criteria are met, confirmatory testing such as apnea testing or cerebral perfusion studies can be performed.⁶⁰ Federal law requires notification of the local organ procurement office prior to formal brain death testing. Medical staff should avoid mentioning organ donation to family members to minimize the appearance of conflict of interest; this is best left to designated requestors after decoupling has occurred.

Patients who have TBI, particularly those who are comatose or have significant non-CNS injuries, are at high risk for pneumonia and other infections, fever, malnutrition, seizures, deep venous thrombosis (DVT), pulmonary embolism, and other maladies endemic to the ICU. Most of these complications cause secondary brain injury and should be diagnosed and treated without delay. Fever is very common in the ICU and has been shown to lengthen length of stay and worsen outcomes.⁶¹ Preclinical studies have found that there is a log increase in neuronal death in ischemic brain regions for every degree of brain temperature above 39°C, and this effect is observed for 24 hours or more after injury.⁶² Consequently, the body temperature should be kept below 37°C at all times, and infectious or other causes of fever should be aggressively sought and treated.

Patients who are comatose, those being maintained on neuromuscular blocking agents, and those with pelvic or long-bone fractures are

at high risk for deep venous thrombosis and pulmonary embolism. They should receive early prophylaxis, which typically includes the use of lower extremity sequential compression devices as well as subcutaneous heparin or enoxaparin. The early (2 to 3 days after injury) use of minidose heparin or low-molecular-weight heparin is safe and has not been found to cause or worsen intracranial hemorrhage after TBI.⁶³⁻⁶⁵

Malnutrition is also common after severe TBI. The resting metabolic expenditure typically increases by 140% in a nonparalyzed patient with severe TBI.⁶⁶ Nitrogen wasting is increased, with excretion of as much as 9 to 12 g/day. Thus, early enteral feeding is advisable, with the aim of providing at least 140% of the daily basal metabolic caloric requirements by the third or fourth day after injury.⁶⁷ For a patient expected to be in a prolonged coma, a percutaneous gastrostomy or surgical jejunostomy provides a convenient and well-tolerated route to administer tube feeding. Hyperglycemia is associated with TBI and is associated with prolonged hospital stays and increased mortality.⁶⁸ Aggressive management of hyperglycemia has been shown to decrease complications and improve long-term outcome,⁶⁹ but the optimal blood glucose range in patients with severe TBI remains controversial, and tight glucose control may be problematic.^{70,71}

Posttraumatic contusions and subdural hematomas are well-known causes of generalized seizures, which can precipitate secondary injury. Anticonvulsant prophylaxis is therefore recommended for patients with these lesions. The drug should be given for the first 7 days after injury; a prospective clinical trial found no advantage to longer prophylactic treatment.⁷² Subclinical seizures may occur in up to 33% of patients in the first week following TBI.⁷³ Therefore, EEG should be considered for those with unexplained depressed mental status, abruptly deteriorating cerebral oxygenation, or a sudden increase in ICP.

Several conditions may lengthen the ICU course of those recovering from severe TBI. Paroxysmal sympathetic hyperactivity, also known as *sympathetic storming*, may become evident when sedation weaning begins in up to 30% of patients. Hallmarks of storming include periodic episodes of seemingly unprovoked hypertension, tachycardia, tachypnea, diaphoresis, and hyperthermia.⁷⁴ Spontaneous posturing or dystonia may also be present during these episodes. Recognition of these symptom complexes as being neurologic in origin is key to avoid treatment delays and unnecessary diagnostic testing. Treatment protocols are individualized, with most patients requiring various combinations of gabapentin, opiates, propranolol, and bromocriptine to achieve adequate symptom control. Posttraumatic agitation (PTA) may follow coma emergence and is a favorable sign for TBI recovery. PTA may delay ventilator weaning, progress with therapy, and impact overall patient safety. Initial treatment should include a certain tolerance for agitation with benzodiazepines administered for emergent control. Ongoing PTA can be treated with agents such as propranolol, tricyclic antidepressants, and antiseizure medications (carbamazepine, valproic acid). Severe cases may require the use of atypical antipsychotics. Haloperidol should be avoided because of its impact on dopamine transmission and subsequent delay in TBI recovery.⁷⁵

PHYSICAL THERAPY AND REHABILITATION

Rehabilitation of TBI patients should begin in the ICU during the first few days after injury and include passive range-of-motion exercises and functional splinting of the extremities. Mobilization helps prevent DVT, and studies indicate that early sitting of comatose patients may hasten the return of consciousness. Recent studies suggest that administration of dopaminergic agents, specifically amantadine, after resolution of intracranial hypertension may hasten arousal and improve outcomes.^{76,77} Comprehensive TBI rehabilitation programs should involve a multidisciplinary team of physical, occupational, and speech therapists, neuropsychologists, and social workers, ideally coordinated by a physiatrist or a neurologist with special training in physical medicine and rehabilitation. Rehabilitation after TBI entails many other factors that are critical to optimizing outcome, but a thorough review is beyond the scope of this chapter.

PENETRATING INJURIES

Gunshot wounds to the head, the predominant cause of penetrating head injury, usually cause massive destruction of brain tissue, severe brain swelling, and if transcranial trajectory, death. The wounding potential of a bullet depends primarily on its velocity at impact and its mass, although the shape of the bullet and its lateral movements also play a role. The impact velocity is by far the most important determinant of a bullet's wounding potential. Consequently, high-velocity rifle wounds to the head are invariably fatal, whereas low-velocity open-chambered handgun wounds often are not. When a bullet enters the skull, it creates a variety of pressure waves within the brain, some of which can cause tissue pressures of nearly 100 atmospheres, resulting in further tissue injury. Bullets often fragment after they strike the skull, fracturing a portion of the skull into multiple fragments. Both the bullet and the bone fragments then become numerous secondary missiles that cause additional tissue damage.

Low-velocity missile wounds, such as those from knives, ice picks, or arrows, do not cause the massive brain injuries seen with bullets. Usually, only the tissue in the immediate path of the missile is damaged, and patients often have a complete neurologic recovery after the missile is surgically extracted. Nonetheless, vascular injuries are always possible with high- or low-velocity missile injuries to the head, especially those in or near the skull base or the sylvian fissures.

The initial assessment and resuscitation of patients with penetrating head injuries are the same as for those with closed head injuries. Knives or other missiles protruding from the head should never be removed in the field or emergency department; if they are tamponading a damaged intracranial vessel, removal could lead to massive intracranial hemorrhage. When a patient has a gunshot wound to the head, the neck, chest, and abdomen should be inspected carefully for other gunshot wounds, because wounds to the heart or great vessels in the chest or abdomen may be even more life threatening. A CT scan of the head defines the intracranial path of the missile and related skull and tissue damage. More importantly, it identifies any large intracranial hematomas or contusions that may significantly affect outcome. If the missile trajectory is in or near the skull base or sylvian fissures and the patient is deemed salvageable, cerebral angiography should be performed because this injury pattern is associated with development of pseudoaneurysm.¹⁰

Most patients who are expected to survive a penetrating head injury require limited operative treatment. Large intracranial hematomas should be evacuated promptly. A craniotomy is required for low-velocity missile wounds in which the object is still protruding from the head. After removing a segment of skull containing the missile and large enough to allow for intracerebral exploration, the surgeon can seek and immediately repair or occlude any vascular injuries caused by the missile. For gunshot wounds to the head, the surgeon should perform a limited débridement of the scalp and skull wound, removing scalp, bone, and bullet fragments penetrating the brain only if they lie near the surface. Easily accessible necrotic brain should be débrided and meticulous hemostasis achieved. Subsequent medical

management of penetrating injuries is as described previously for closed head injuries. Because a penetrating TBI by definition disrupts and contuses brain tissue, all patients with these injuries should also receive anticonvulsants for at least 7 days.⁷²

PROGNOSIS

Predicting outcome soon after a TBI can help guide acute and chronic care and help prepare family members for the typically protracted recovery process. Equally important is that further treatment may be deemed futile, and expensive critical care or surgery can be reserved for those who are likely to benefit. Of course, early prognostication must be reliable, especially when withdrawal of life support is a consideration.

Several clinical and radiographic characteristics have proven useful for outcome prediction, but they must be used in concert.⁷⁸ Moreover, these criteria are more reliable for predicting death or vegetative survival than for accurately predicting mild or no dysfunction and a complete return to normalcy. The most powerful outcome predictors are age, initial GCS score (particularly the motor component), pupil size and reaction to light, ICP, and the nature and extent of intracranial injuries.

Marshall and colleagues devised a CT-based classification scheme that proved prognostically useful when applied to the patients in the Traumatic Coma Data Bank study (Tables 56-2 and 56-3).⁷⁹ The classification emphasizes the mass effect of posttraumatic intracranial lesions. Not surprisingly, these investigators found the worst outcomes among patients with large intracranial mass lesions and uncal herniation.

The patient's salvageability and prognosis after a penetrating injury are far clearer than for those with closed head injuries. Most victims of high-velocity gunshot wounds to the head die before or shortly after

TABLE 56-2

Computed Tomographic Classification of Traumatic Brain Injury

| CATEGORY | DEFINITION |
|-------------------------------|--|
| Diffuse injury I | No visible intracranial pathology |
| Diffuse injury II | Cisterns present, with midline shift 0 to 5 mm; no high-density lesion >25 mL |
| Diffuse injury III (swelling) | Cisterns compressed or absent, with midline shift 0 to 5 mm; no high-density lesion >25 mL |
| Diffuse injury IV (shift) | Midline shift >5 mm; no high-density lesion >25 mL |
| Evacuated mass lesion | Any lesion surgically evacuated |
| Nonevacuated mass lesion | High-density lesion >25 mL; not surgically evacuated |

Data from Marshall LF, Marshall SB, Klauber MR, Clark M. A new classification of head injury based on computerized tomography. *J Neurosurg* 1991;75:S14–S20.

TABLE 56-3 Relationship of Computed Tomographic Classification to Outcome at Discharge

| CATEGORY | NO. OF PATIENTS | UNFAVORABLE OUTCOME* (%) | FAVORABLE OUTCOME† (%) |
|--------------------|-----------------|--------------------------|------------------------|

Data from Marshall LF, Marshall SB, Klauber MR, Clark M. A new classification of head injury based on computerized tomography. *J Neurosurg*. 1991;75(Suppl.):S14–S20.

*Death, persistent vegetative state, or severe disability.

†Moderate disability or good recovery.

hospital admission. A meta-analysis of recent clinical studies examining civilian gunshot wounds to the head found that favorable outcomes (Glasgow Outcome Scale scores of 4 or 5) occurred in only 5 of 490 patients with initial GCS scores of 3 to 5.⁸⁰ Mortality rates ranged from 51% to 87% for patients with scores of 8 or less. In contrast, those whose initial GCS scores were 13 to 15 all survived and had favorable outcomes. Other clinical signs associated with death or a poor outcome are fixed and dilated pupils, intracranial hypertension, and hypotension.

The CT-defined extent of intracranial injury caused by the missile also has prognostic significance. Hyperdense lesions with a volume greater than 15 mL, midline shift of more than 3 mm, compressed or absent basal cisterns, subarachnoid hemorrhage, and intraventricular hemorrhage are all associated with mortality rates of 80% to 90%, as is a bullet trajectory that traverses both hemispheres, the basal ganglia, or the posterior fossa.^{81,82}

KEY POINTS

1. Severe traumatic brain injuries are the leading cause of morbidity and mortality for Americans between the ages of 1 and 45 years.
2. Outcome following traumatic brain injury is determined not only by the primary injury, such as skull fracture and subdural hematoma but also by secondary injuries initiated by posttraumatic ischemia.
3. Secondary brain injuries are primarily responsible for the development of delayed intracranial hypertension.
4. The goal of critical care management of patients with severe traumatic brain injury is to enhance cerebral perfusion and avoid therapy that may cause regional cerebral ischemia.
5. Early assessment and triage of patients with severe traumatic brain injury should use the advanced trauma life support protocol prescribed by the American College of Surgeons Committee on Trauma.
6. Patients with severe traumatic brain injury are best managed at a level I trauma center with immediate neurosurgical availability.
7. Patients with contusions or hematomas visible on head computed tomography scans and Glasgow Coma Scale scores of 8 or less benefit from intracranial pressure monitoring.
8. A ventricular catheter coupled to an external strain-gauge transducer is the optimal means of monitoring intracranial pressure, because it provides accurate measurements and allows for CSF drainage—the most benign way of treating elevated intracranial pressure.
9. Prophylactic hyperventilation therapy, particularly when the intracranial pressure is less than 20 mm Hg, should be avoided.
10. Patients with subdural hematomas, contusions, or penetrating injury benefit from anticonvulsive prophylaxis for 7 days after injury.
11. Early evaluation of brain-injured patients by a physical therapist and rehabilitation specialist is highly recommended to prevent immobility-related complications and facilitate rapid mobility.

ANNOTATED REFERENCES

Chestnut RM, Marshall SB, Piek J, et al. Early and late systemic hypotension as a frequent and fundamental source of cerebral ischemia following severe brain injury in the Traumatic Coma Data Bank. *Acta Neurochir Suppl (Wien)* 1993;59:121–125.

The authors reviewed blood pressure readings in a group of several hundred patients admitted to the Traumatic Coma Data Bank. They found that hypotension (systolic blood pressure <90 mm Hg) was associated with a twofold increase in the mortality rate compared with head-injury patients who did not have hypotension.

Haas B, Jurkovich GJ, Wang J, Rivara FP, Mackenzie EJ, Nathens AB. Survival advantage in trauma centers: expeditious intervention or experience? *J Am Coll Surg* 2009;208(1):28–36.

In a multicenter prospective cohort study of 1331 adult trauma patients cared for in trauma centers (TC) and nondesignated centers (NTC), times from admission to relevant interventions were assessed, as were relative risks of in-hospital death. The relative risk of death was 0.61 (95% CI,

0.43–0.86) among patients managed at TC compared with those admitted to NTC. This survival advantage was greatest among patients with penetrating trauma, though the relative risk of death at a TC among patients in the TBI group was 0.72 (95% CI, 0.50–1.0). These outcomes were not a result of more rapid assessment and intervention alone and emphasize the complex factors that contribute to the survival benefit of trauma center care.

Temkin NR, Dikmen SS, Wilensky AJ, et al. A randomized, double-blind study of phenytoin for the prevention of posttraumatic seizures. *N Engl J Med* 1990;323(8):497–502.

In this randomized, controlled, double-blind study of the benefit of prophylactic anticonvulsant therapy for patients with TBI, the authors found a significant reduction in the incidence of posttraumatic seizures during the first week of therapy, but no subsequent benefit was observed when therapy was continued longer than 7 days. This study has led most to discontinue the use of anticonvulsants 1 week after TBI, regardless of the nature of the injury.

Despite substantial improvements in emergency, diagnostic, and surgical care, spinal trauma continues to present a challenging spectrum of diseases for the neurosurgeon to manage. When spinal trauma results in a spinal cord injury (SCI), the emotional and financial toll inflicted on individuals and their families is enormous. Improvements in the quality of care delivered over the past few decades are partially reflected in the recognition that centers of excellence that focus on acute treatment and rehabilitation of the patient with SCI are best equipped to deal with the magnitude of services these patients require.

■ EPIDEMIOLOGY

Spinal cord injury typically occurs in males at the peak of their productive lives. The incidence of traumatic SCI is approximately 11,000 new cases each year in the United States,¹ with a prevalence of 191,000. The prevalence is increasing steadily owing to improved survival in both the acute and chronic stages of the disease. Depending on the age at injury, level, and severity of injury, life expectancy ranges from 4 to 50-plus years after injury. The cost of caring for the individual patient is directly related to the injury level of the spinal cord and to the patient's age, with the highest costs associated with older quadriplegic patients who are dependent on a ventilator.

The estimated lifetime cost for one person injured at the age of 25 with a high cervical injury is more than \$4.6 million.² Only 12%-24% of people with SCI return to work. Thus, the combination of increased survival, extensive medical expenses, and high unemployment has resulted in SCI becoming a significant public health burden. It is estimated to cost the United States at least \$9.7 billion annually.³

■ ETIOLOGY

Most spinal injuries result from high-speed motor vehicle accidents (Fig. 57-1). Falls and work-related injuries are other contributors. Spinal cord injury that is due to violence is on a dramatic rise secondary to an increased incidence of assaults. These injuries include both blunt and penetrating injuries, such as gun and knife wounds. Sports-related injuries, which include football, horseback riding, and hockey injuries, are relatively rare but receive media attention.^{4,5} Finally, recreational injuries from jet skis, snowmobiles, snow skiing, snowboarding, and parachuting, to name but a few, are on the rise as extreme sports become more prevalent.

■ INITIAL MANAGEMENT

Suspected SCI alters the basics of the ABCs of resuscitation in several important ways. With respect to airway management, suspected SCI dictates in-line immobilization of the spine at all times, so hyperextension of the neck is contraindicated. A jaw thrust must be used to open the airway, and required intubation must be done with the head and neck in a neutral position. This is an important point to remember because patients with a high SCI will have diminished or absent respiratory capacity and frequently require emergent intubation.

Aggressive resuscitation of patients with SCI proceeds as with all trauma patients. Upper SCI may be associated with neurogenic shock, requiring large-volume fluid replacement. Although pressors are likely

to be required in the setting of neurogenic shock, field management is commonly limited to fluid resuscitation. The high incidence of associated head injury often requires careful titration of fluids to resuscitate the patient adequately while minimizing exacerbation of cerebral edema.

IMMOBILIZATION AND DIAGNOSTIC EVALUATION

Rigid immobilization is indicated if there is any suspicion of the presence of SCI. The presence of altered mental status dictates the use of spinal cord precautions. These include use of in-line immobilization, maintenance of neutral position, cervical immobilization with a rigid collar, and use of backboards for transport.

After initial resuscitative efforts, diagnostic studies are undertaken. Fine-cut helical computed tomography (CT) with coronal and sagittal reconstructions have supplanted plain radiographs in most trauma centers as an initial evaluation for detecting spine fractures. Additional spine studies may be obtained after the patient has been stabilized and more emergent diagnostic studies have been undertaken. During this time, rigid cervical collar and backboard immobilization must be continued.

Further diagnostic studies will be dictated by the findings of the initial and secondary surveys as well as findings of initial diagnostic studies. Several points are important to keep in mind. First, important information can be obtained from studies performed for other reasons. For example, routine chest and abdominal radiographs may provide important information regarding the presence of significant thoracic or lumbar spine injury. Although these do not replace subsequent formal spine studies, they are often obtained as part of the routine trauma workup, may provide early clues to the presence of spine trauma, and may help prioritize subsequent imaging studies. Radiographs and particularly CT are the most sensitive tools in detecting a fracture of the spine, but occasionally it is difficult to clear the spine—that is, to rule out a spinal injury—even in the absence of a fracture because an unstable ligamentous injury may exist without a fracture.

Clearing the unconscious patient with high-resolution CT scans of the spine has greater than 99.9% sensitivity and specificity, indicating that CT alone is sufficient in detecting unstable C-spine injuries in patients with trauma.⁶ Magnetic resonance imaging (MRI) of the spine is used to quantitate ligamentous injuries and to rule out a hematoma or a disk herniation and to assess the degree of spinal cord compression. Malalignment and evidence of spine trauma on these imaging studies frequently determines subsequent management and diagnostic decision making. Cervical subluxations often require the use of traction or manual reduction of the fracture-dislocation. Diazepam or lorazepam, along with careful neurologic monitoring, often in the intensive care unit (ICU) setting, is required because application of traction can realign the spine but can also result in neurologic deterioration.

■ PEDIATRIC SPINAL CORD INJURY

Pediatric spine trauma is relatively uncommon, representing approximately 5% of all SCIs.⁷ For a specific discussion of pediatric SCI, please see Chapter 172. Guidelines have been published on this topic.⁸

FIGURE 57-1 ■ **A**, Sagittal CT demonstrates an L3 burst fracture that presented with cauda equina syndrome. **B**, Axial CT demonstrates severe compression of the spinal canal. **C**, The canal was decompressed surgically with a minimally invasive approach resulting in significant root recovery.

■ PHARMACOTHERAPY

The concepts of primary and secondary SCI are important principles in understanding the pathophysiology and the role of pharmacotherapeutic agents in emergency treatment. The primary injury results from a mechanical insult that occurs at the time of impact and includes acute compression, impaction, distraction, laceration, and shear.⁹ Secondary injuries occur after the initial injury and account for some of the progressive pathologic changes associated with SCI that, if left untreated, can potentially result in limited recovery.⁹ A number of drugs have been tested in the laboratory, but only a few of these agents have progressed to clinical trials to evaluate their efficacy. Five randomized controlled trials of pharmacotherapy for acute SCI have been conducted, focusing on the therapeutic effect of either corticosteroids or gangliosides.

Corticosteroids and Gangliosides

A number of studies have shown improved neurologic recovery in animals with SCIs that have received either dexamethasone or methylprednisolone.¹⁰⁻¹³ Corticosteroid treatment initially held promise as a potential therapeutic agent for its putative role in reducing white matter edema and inflammation. Current evidence, however, suggests that the major mechanism of action is reduction of the effects of secondary injury, in particular, the destructive effects of lipid peroxidation on cell membranes.³ Other actions include improving spinal cord blood flow, enhancing the postinjury activity of Na^+/K^+ -ATPase, and facilitating the recovery of extracellular calcium ion.^{13,14}

The first NASCIS trial (NASCIS I) examined low- (100 mg) and high- (1000 mg) dose methylprednisolone given to patients with acute SCI for 10 days. Unfortunately, this trial had no control group, and no significant difference in outcome was found except for an increased number of wound infections among patients in the high-dose group.¹⁵ The second NASCIS trial (NASCIS II) was a prospective, randomized, double-blind, multicenter trial that showed improved neurologic outcomes after 6 weeks, 6 months, and 1 year in patients with nonpenetrating SCI who had received a methylprednisolone regimen, which included a bolus of 30 mg/kg.¹⁶ Improvement in motor and sensory scores associated with administration of methylprednisolone compared to naloxone or placebo was seen, but only if the drug was given within 8 hours of injury. Results of this study have been criticized.^{17,18}

Some of the questions relate to difficulties in randomization, reporting methods, analysis of benefit limited to small subgroups within the larger study, and lack of replication of results by an independent group of investigators, among others. The results of NASCIS III suggest that when patients are seen within 3 hours of their injury, they should receive a bolus dose of methylprednisolone (30 mg/kg intravenously [IV]) followed by 23 hours of treatment (5.4 mg/kg/h IV). Patients seen between 3 and 8 hours should receive the same bolus followed by a longer dosing regimen (48 hours). Complications from 48 hours of treatment included a significant increase in severe sepsis and pneumonia.¹⁹ The most recent neurosurgical guidelines for management of spine trauma do not recommend methylprednisolone as a treatment option, recognizing that the risks of use have been more clearly demonstrated than the benefit.²⁰ A prospective, randomized, double-blind, single-center study found a beneficial effect on functional neurologic outcomes when the ganglioside GM-1¹ was administered within 72 hours of human SCI.²¹ However, a multicenter trial showed no statistically significant benefit from this agent at 26 and 52 weeks after injury.²²

■ HYPOTHERMIA

Three recent studies were published on the safety and feasibility of mild to moderate intravascular cooling for SCI. Levi et al. reported on a series of 14 patients with American Spinal Injury Association (ASIA) classification A complete cervical cord injuries who underwent a protocol to achieve temperatures of 33.5°C using a closed-loop delivery system. The investigators found good correlation between intravascular and intrathecal cerebrospinal fluid temperature.²³ The average time between injury and induction of hypothermia was 9.17 ± 2.24 hours (mean \pm SEM), time to target temperature was 2.72 ± 0.42 hours, duration of cooling at target was 47.6 ± 3.1 hours, and total length of time of cooling was 93.6 ± 4 hours. A subsequent paper summarized the complications and neurologic outcomes in this initial group of patients treated with hypothermia and compared them to age- and injury-matched controls.²⁴ Approximately 42% of patients treated with hypothermia had improvement in their ASIA stage, with a frequency of cardiovascular complications similar to that of historic matched controls.²⁵ The most recent work includes a larger series ($n = 35$) of patients, of whom a similar proportion had an improved ASIA grade.²⁶ This has led the Joint Section of Spine and Peripheral Nerves to issue

a position statement that the current data provide level IV evidence for its use (www.spinection.org).

■ INTENSIVE CARE UNIT MANAGEMENT

Spinal cord injury is associated with profound effects on all vital system functions. With primarily class III medical evidence, numerous reports indicate lower morbidity and mortality rates in patients with SCI managed with ICU monitoring and aggressive medical management of physiologic changes.²⁷⁻³⁵ At the very least, these studies taken together indicate that a systematic approach must be taken to evaluate and treat each of the potential complications. Early and late complications will be seen, and the degree of involvement of each system is usually correlated with the level and severity of injury.

Respiratory System

Respiratory complications are a major source of morbidity and mortality after SCI, with an 18% to 30% mortality rate reported in patients with tetraplegia.^{30,36} In a study by Hachen and associates,^{28,34} most early deaths were related to pulmonary complications, with the likelihood of severe respiratory insufficiency related to SCI severity. Whereas most cervical spinal cord injuries occur below C4, so that the phrenic nerves continue to innervate the diaphragm, the respiratory system is frequently severely affected, particularly after cervical spinal cord injuries. Specifically, marked reductions in (forced) vital capacity, inspiratory capacity, and expiratory flow rates frequently result in hypoxemia.^{30,34,37,38-40} These changes may be attributed to variable paralysis of the intercostal muscles and accessory muscles of respiration. Loss of abdominal muscle tone and ileus also reduce the mechanical efficiency of breathing.

In general, there is a grace period in which patients with cervical SCI will maintain their respiratory status. However, respiratory failure can ensue 24 to 48 hours after admission. Additional injuries, such as rib fractures and hemothorax, can accelerate this respiratory deterioration. Preparation for such events should be undertaken early so that if intubation is required, it can be done with cervical stabilization using in-line traction, often supplemented by use of a fiberoptic intubation technique. Measurement of arterial blood gases, negative inspiratory force, and forced vital capacity may facilitate early detection of respiratory failure.

The most common respiratory complications include atelectasis, pneumonia, pulmonary embolus, pulmonary edema, and acute respiratory distress syndrome. In addition to difficulty taking deep breaths and coughing, patients are often unable to clear airway secretions. Accumulation of secretions and mucous plugs can result in respiratory failure. Prevention includes respiratory treatment with bronchodilators, frequent pulmonary toilet, chest physiotherapy, increasing airway humidity, intubation, and mechanical ventilation including the use of continuous positive airway pressure. The use of the RotoRest bed significantly decreases pulmonary complications associated with SCI^{30,41} because it improves pulmonary blood flow and reduces the incidence of pulmonary emboli.

Pulmonary infections often complicate SCI. Within days of admission, the normal flora of the oral cavity will contain increasing numbers of nosocomial organisms. Hospital-acquired pulmonary infections are heralded by fever, increased white blood cells in both sputum and peripheral blood, and changes on the chest radiograph. After obtaining appropriate cultures, treatment with broad-spectrum antibiotics should be instituted.

Most patients can be weaned from the ventilator after they have been medically stabilized, which usually means treatment of pulmonary infections, reestablishment of euolemia, enhancement of respiratory muscle function, and nutritional supplementation to offset the high caloric requirements of the trauma. Initially, weaning with intermittent mandatory ventilation is followed by weaning with positive airway pressure (either continuous or end expiratory). With prolonged periods of ventilation (>2 weeks) or multiple failed extubations, one

should consider a tracheostomy. The likelihood of requiring a tracheostomy increases with a high SCI, preexisting pulmonary disease, and the age of the patient. Tracheostomy effectively reduces the physiologic dead space.

Cardiovascular System

Significant confusion arises when the term *spinal shock* is used after SCI. The misunderstanding regarding its use stems from multiple causes. First, many physicians use the terms *spinal shock* and *neurogenic shock* interchangeably. Neurogenic shock, however, refers to a condition characterized by hypotension and bradycardia resulting from interruption of the sympathetic nervous system pathways within the spinal cord. The incidence of significant neurogenic shock increases with injuries above the T6 level, because unopposed vagal tone slows the heart and reduces systemic vascular resistance, resulting in venous pooling. The condition responds to administration of fluids or colloids and occasionally requires the use of pressors. Neurogenic shock is distinct from hypovolemic shock, which may occasionally occur concomitantly in the patient with SCI and multiple trauma who has evidence of either external or internal bleeding. Whereas isolated hypovolemic shock is characterized by hypotension with tachycardia, relative bradycardia (for a given degree of hypotension) is to be expected in the setting of multiple trauma with SCI.

Spinal shock encompasses a number of different neurologic manifestations of SCI with varying time courses. Traumatic injuries to the spinal cord interrupt or temporarily damage a number of descending and ascending pathways. The most common initial presentation of a complete SCI with respect to reflex and autonomic function is a period of areflexia and flaccidity that is gradually replaced by hypertonia, exaggerated reflexes, and (in many cases) spasticity. The transition period may last from days to weeks. The immediate onset of hyperreflexia and spasticity is uncommon; when it occurs, it is a bad prognostic sign. This period of transition in reflex and autonomic function is often referred to as *spinal shock*. Concomitant changes in motor and sensory function are also common.

Animal studies indicate that ischemia underlies many of the secondary mechanisms affecting patients post SCI, often dictating the resultant deficits.^{34,42-44} Human studies suggest a direct correlation between the severity of SCI and the incidence and severity of cardiovascular problems.^{34,45} Together, this suggests that reducing the magnitude of secondary injury should be at the forefront of medical management of SCI.

The typical patient with SCI without associated vascular or visceral injury presents to the emergency department with a mean arterial blood pressure of 80 mm Hg and a heart rate of 65 beats/min.³³ Persistent bradycardia is a frequent finding and is often profound enough to produce hemodynamic compromise.^{25,34} The patient's blood pressure may respond to volume resuscitation, but often these patients also require low-dose pressors. Aggressive medical management, including volume expansion and maintenance of mean arterial blood pressure greater than 85 mm Hg, is believed to potentially enhance neurologic outcome by maximizing spinal cord perfusion at the injury site, thus reducing the likelihood of secondary injury.⁹ Invasive hemodynamic monitoring will usually demonstrate a normal cardiac index with low systemic vascular resistance. In the elderly patients with SCI, careful attention to volume replacement is required so as not to precipitate heart failure.

Gastrointestinal System

Hypoactive bowel sounds and impaired peristalsis are common after SCI, owing to the lack of sympathetic modulation. To avoid gastric and small-bowel dilatation, it is wise to delay enteral feeding. When gastric distention impairs respiratory function, a nasogastric tube is indicated. Most cervical cord injuries require nasogastric suction because of impaired bowel motility, air swallowing producing gastric distention, and respiratory compromise due to intercostal muscle paralysis.

Patients with SCI are at high risk of developing gastric and duodenal stress ulcers. Use of steroids compounds the risk of significant gastrointestinal hemorrhage.⁴⁶ All patients with SCI should at minimum receive an H₂ blocker to prevent this dreaded complication. The reported risk of gastrointestinal hemorrhage in NASCIS II for the control group was 3% and for the methylprednisolone group, 4.5%.¹⁶

Urinary System

During the period of spinal shock after a cervical or thoracic SCI, the urinary bladder is atonic and flaccid. Over time it becomes an upper motor neuron bladder with small capacity. An indwelling Foley catheter is initially placed. After 3 to 4 days this is switched to intermittent bladder catheterization to maintain urinary volumes below 500 mL. Urinary tract infections are common, and if fever occurs, urine cultures must be obtained and antibiotics selected based on culture and sensitivities. Patients with spinal injuries above T6 may also develop autonomic dysreflexia if the bladder becomes overdistended or sometimes with catheterization. The result may be sympathetic overactivity, with headaches, hypertension, sweating, and reduced body temperature. Long-term complications include chronic infections, obstructive uropathy, and renal calculi; if left untreated, renal failure may develop.

Integument

The SCI patient is extremely susceptible to developing decubitus ulcers. Frequent log rolling is invaluable in preventing skin breakdown. Specialized beds to turn patients with SCI (e.g., RotoRest⁴¹ [KCI Therapeutic Support Systems, San Antonio]) can reduce the incidence of skin breakdown by preventing pressure on a single area. Early intervention for skin breakdown frequently involves application of the DuoDERM patch (ConvaTec, Princeton, NJ) to prevent progression.

Thromboembolic Complications

Patients with SCI are at high risk of venous thromboembolism, which may manifest as deep vein thrombosis (DVT) in the lower or upper extremities and lead to swelling and possibly to pulmonary embolism. Depending on injury severity, age, and diagnostic methods, the reported incidence of thromboembolic events ranges from 7% to 100%.⁴⁷ The majority of these events occurs within the first 3 months after injury, except in patients who are elderly, obese, or who have had prior thromboembolic events.⁴⁷ Numerous studies have addressed the issue of preventive measures for DVT. Prevention has traditionally included the administration of low doses of heparin (5000 units subcutaneously) twice daily or more. However, meta-analysis of the available literature suggests that better alternatives include the combination of pneumatic compression stockings with low-molecular-weight heparin or adjusted-dose heparin.⁴⁷

Current recommendations for evaluation of suspected thromboemboli include use of Doppler ultrasound for suspected DVT and venography if a strong clinical suspicion exists for DVT despite a negative ultrasound or if pulmonary embolism is suspected.^{47,48} Treatment of pulmonary emboli or above-the-knee DVT requires heparinization. Should there be a contraindication to heparin, an inferior vena cava filter should be placed. Prophylactic placement of inferior vena cava filters has been advocated,^{24,47,49,50} but these procedures are not without risk, and no study thus far compares success rates to the aforementioned conservative prevention modalities.^{1,44}

PROGNOSTIC FACTORS FOR RECOVERY

The clinician uses the neurologic examination, patient age, and appearance of the spinal cord on MRI as well as other clinical data to advise the patient and family on the expected outcome for a specific injury. In any traumatic SCI, it is important to ascertain whether the patient has a functionally complete or incomplete neurologic deficit. The distinction is important because the prognosis for neurologic recovery

differs for these two conditions. Patients with no evidence of motor or sensory function below the level of their injury are considered to have functionally complete injuries. No voluntary motor control and only slight sensory preservation in the lowest sacral dermatomes or some anal tone are considered to be an incomplete injury. Functionally, patients with complete cervical SCI whose deficits remain complete in the first 24 hours of admission are unlikely to regain significant ambulatory function (1% to 3%).^{52,53} However, most patients who enter the hospital with an incomplete neurologic injury attain some degree of recovery. The level and degree of an incomplete injury also provide important prognostic information. Cervical injuries have a higher potential for recovery when compared with thoracic or thoracolumbar injuries. The less severe the SCI, the more likely the patient will recover.⁵⁴

The majority of injuries occurs in males, with well over half occurring in the 16- to 30-year-old age group. Prognosis for recovery is inextricably linked to age, with younger patients faring much better than their older counterparts in regaining neurologic function after SCI.^{55,56} The two most important potential neurologic explanations are the capacity of the young spinal cord to function with major deficiencies in the neural circuitry and the possibility of some spontaneous regeneration of the CNS after injury.⁵⁷ The reverse also appears to be true. It is well recognized that patients with stable incomplete injuries may lose function as they age, and this may simply result from loss of the last few functioning neurons or axons in the damaged region of the spinal cord.⁵⁸ Neuronal loss is a normal part of aging in both brain and spinal cord, and the clinical deterioration seen after SCI may be likened to the postpolio syndrome.

MRI after SCI allows noninvasive visualization of the spinal cord (Fig. 57-2). The images provide immediate feedback to the surgeon about the degree of spinal cord compression, as well as information regarding the stability of the spinal column through an assessment of the integrity of the ligaments, disks, and surrounding soft tissues. In addition, intramedullary hemorrhage may be easily discerned, providing important prognostic information. Intramedullary hemorrhage is more commonly observed after neurologically complete injuries, and hemorrhage signifies a worse neurologic and functional outcome.^{59,60} MRI of SCI is discussed in greater detail in Chapter 38.

FIGURE 57-2 ■ Sagittal T2-weighted MRI demonstrates a C6-C7 fracture-dislocation with severe cord compression in a patient who presented with complete C6 quadriplegia-ASIA.

RESEARCH

Spinal cord injury research is an absolute priority of the National Institutes of Health. Models of SCI, mechanisms of secondary injury, treatment of the acute phase of SCI, and development of transplantation strategies to repair a damaged spinal cord are ongoing across North America and around the world. The treatment arms of research can be divided into two categories: (1) agents that can be given during the acute phase of injury to limit secondary injury mechanisms and (2) strategies to promote regeneration. What were thought to be two of the most promising drugs, methylprednisolone and ganglioside GM₁,¹ have yielded only modest results. Methylprednisolone, which is used in almost all major SCI centers, is coming under closer scrutiny as to its effectiveness.¹⁷ Drugs of the future include neurotrophins, which can promote survival and regeneration of injured nerve cells, drugs that prevent the inflammatory response to SCI,⁵⁹ and drugs that prevent apoptotic cell death.⁶¹ In the transplantation arena, cellular therapies to treat chronic injury are important. Cells of interest include Schwann cells, olfactory ensheathing glia, embryonic spinal cord, and neural progenitor cells. Antibodies that neutralize inhibitory proteins in myelin have also shown promise. Combination therapy is most likely to show benefit in the future.

CONCLUSION

It appears that despite enormous advances in the diagnosis and treatment of spinal fractures over the past 3 decades, there exist a number of unanswered questions regarding the most appropriate management of patients with traumatic spinal fractures. Although only a few aspects of the surgical management of spine trauma are raised in this chapter, it is clear a number of issues remain unresolved.

Technologic advance in spinal instrumentation and pharmacotherapeutics will continue in the 21st century. It is vital that neurosurgeons

and orthopedic surgeons work together to test both the efficacy and cost-effectiveness of some of the newer treatment modalities, because both the best possible treatment and cost containment will be part of the management equation in the future. Outcome assessment should be at the forefront of all new ideas. Only through a critical and open-minded analysis of our treatment strategies will we be able to provide the best care for these patients who will often be disabled for the remainder of their lives by their injuries. Applying the best strategies is a particular challenge because of the rapid sequence of events that revolve around these patients' acute hospitalization.

KEY POINTS

1. Most spinal injuries result from high-speed motor vehicle accidents.
2. The primary mechanisms of injury are mechanical insults that occur at the time of impact and may include acute compression, impaction, distraction, laceration, and shear. Secondary injuries occur after the initial injury and account for some of the progressive pathologic changes associated with spinal cord injury (SCI).
3. Respiratory complications are a major source of morbidity and mortality after SCI.
4. In the elderly patient with SCI, careful attention to volume replacement is required so as not to precipitate heart failure.
5. The prognosis for recovery and survival from SCI is inextricably linked to age, with younger patients faring much better than their older counterparts.

This chapter reviews available neuroimaging methods and their application to children with suspected neurologic disorders

METHODS

Plain Radiographs

Plain radiography quickly identifies surgical or unstable traumatic injuries. However, computed tomography (CT) or magnetic resonance imaging (MRI) is necessary when intracranial or intraspinal injury is suspected.¹

Computed Tomography

CT is widely available, rapid, and accurate, with virtually no contraindications in the acute setting. The radiation risk should be considered in young patients and patients likely to require numerous studies.² Rapid acquisition usually makes sedation unnecessary. Axial images can be reconstructed along other planes. Iodinated IV contrast can be given to identify areas of blood-brain barrier breakdown and, with angiography (CTA), to visualize blood vessels. CT perfusion can estimate cerebral blood volume (CBV), cerebral blood flow (CBF), and mean transit time.³

Magnetic Resonance Imaging

MRI uses an intense magnetic field without ionizing radiation. MRI “sequences” vary the imaging parameters to highlight different anatomic and physiologic properties.⁴ Gadolinium-based, noniodinated IV contrast agents are used although there are no concerns about their extravasation into brain tissues. MR angiography (MRA) and qualitative MR perfusion-weighted imaging (PWI) can be done without IV contrast.

Functional MRI (fMRI) analyzes CBF during task performance or in the resting state. Diffusion-weighted imaging (DWI) evaluates the freedom of water molecule movement. Increased diffusion is seen in areas with fewer cells or increased extracellular water, and restricted diffusion is seen in areas with tightly packed or swollen cells. Water also diffuses more freely parallel to well-organized white matter tracts. DWI can be used to identify acute ischemia, differentiate necrotic tumor from abscess, and grade tumors.^{5–7} PWI studies can show areas of reduced perfusion that may respond to reperfusion.^{8,9}

Magnetic resonance spectroscopy (MRS) measures metabolites that can help characterize a lesion or grade its severity.^{10,11} Diffusion tensor imaging (DTI) can map white matter fiber tracts and their relation to lesions and to planned surgeries.¹²

Patients with ferromagnetic metal devices, prostheses, or fragments cannot be exposed to the powerful MRI magnet.¹³ Some patients may be too unstable to leave the intensive care unit long enough for an MRI.

Nuclear Medicine Studies

Positron emission tomography (PET) and single photon emission computed tomography (SPECT) are used to measure cerebral metabolism and/or perfusion.¹⁴ PET studies are easier to coregister with MRI

but require the use of isotopes with shorter half-lives that are not widely available. PET is useful in diagnosis, staging, and monitoring of tumors and in the surgical evaluation of intractable epilepsy.^{15,16} SPECT is often used to assess CBF in suspected brain death.¹⁷

Angiography

Conventional angiography using percutaneous transfemoral catheterization, injected iodinated contrast, and fluoroscopy is the gold standard for evaluating cerebral and spinal vessels. While invasive, serious complications are rare.^{18,19}

BRAIN

Patterns of Disease

Edema

Cerebral edema can be divided into three types, defined as follows:

1. Vasogenic: water from leaky capillaries
2. Cytotoxic: water within swollen cells injured by energy failure
3. Interstitial (transependymal): water crossing from the ventricles into the parenchyma

Increased water content appears dark on CT because of hypodensity. It also appears dark on T1-weighted imaging (T1WI) but bright on T2-weighted imaging (T2WI), including fluid-attenuated inversion recovery (FLAIR) studies in which the CSF appears dark. Vasogenic edema extends along white matter tracts, creating “fingers” extending toward the cortex (Fig. 58-1). This edema does not follow a vascular distribution and often has a mass effect. Cytotoxic edema often follows a vascular distribution and produces less mass effect (Fig. 58-2). DWI shows increased diffusion with vasogenic edema and restricted diffusion with cytotoxic edema. Interstitial edema is best seen on FLAIR.²⁰ Increased CBV can mimic edema but is differentiated by perfusion studies.²¹

Hemorrhage

The appearance of hemorrhage depends most on timing. On CT, hemorrhage may be isodense in the hyperacute stage, then hyperdense within hours (Fig. 58-3A) before becoming isodense again over days and then hypodense over weeks (Table 58-1). Acute hematomas may remain isodense longer in anemia or coagulopathy.^{22,23} Remote hemorrhage can be inapparent on CT or appear hypodense due to tissue injury or hyperdense due to calcification.

The evolving MRI appearance of hemorrhage results from hemoglobin (Hb) metabolism. Acutely, oxy-Hb appears hypo- to isointense on T1WI and iso- to hyperintense on T2WI. As Hb becomes deoxygenated, it appears hypointense on T2WI. In the subacute stage, Hb is broken down to intracellular methemoglobin, which appears hyperintense on T1WI and hypointense on T2WI. As red blood cells lyse and release methemoglobin, its signal becomes hyperintense on T1WI and T2WI. In the chronic stage, methemoglobin is degraded to hemosiderin, appearing hypointense on T1WI and T2WI (Figs. 58-3B and C).⁷ Susceptibility-weighted imaging (SWI) has made MRI more sensitive for hemorrhages.²⁴

Intraparenchymal bleeds are associated with surrounding vasogenic edema and can expand significantly in the first 3 hours,²⁵

FIGURE 58-1 ■ Vasogenic edema in glioblastoma. Non-contrast-enhanced axial computed tomography scan (**A**), axial T1-weighted magnetic resonance imaging (MRI) scan (**B**), and axial T2-weighted MRI scan (**C**) all demonstrate an area of edema (E). Edema extends along white matter fibers (dots), with normal gray matter interposed. Axial T1-weighted MRI scan following contrast enhancement (**D**) demonstrates the enhancing tumor nidus (arrow), distinct from surrounding edema. Subfalcine herniation is also demonstrated on these images by displacement of the falx (curved arrows).

especially when the hematoma shows initial contrast enhancement.²⁶ Vasogenic edema can expand significantly over several days.

Mass Effect, Shift, and Herniation

Intracranial lesions can lead to brain herniation as a result of lesion growth, vasogenic edema, or obstructive hydrocephalus.²⁷ The dural partitions within the skull, the falx cerebri and the tentorium cerebelli, create compartments across which the brain may herniate.

Subfalcine herniation occurs when the medial surface of a hemisphere is pushed under the falx. Early imaging signs may show lateral ventricular distortion (see Fig. 58-1). Later stages show deviation of the falx, structures crossing the midline, and ischemia from compression of the anterior cerebral artery.

Transalar herniation occurs when brain tissue is pushed above (ascending) or below (descending) the ridge of the greater sphenoid wing, which may lead to ischemia from compression of the middle cerebral artery.

Transtentorial herniation can also be ascending or descending. Downward herniating brain can push against and rotate the brainstem, producing widening of the ipsilateral brainstem cistern and effacement of the contralateral cistern (Fig. 58-4). The contralateral temporal horn may dilate secondary to trapping. Ascending transtentorial herniation

often causes symmetric effacement of the brainstem cisterns, compression of the cerebral aqueduct, and acute hydrocephalus.

Tonsillar herniation through the foramen magnum can result in brainstem compression.

Specific Disease Processes

Traumatic Brain Injury

Noncontrast head CT continues to be the primary modality for initial evaluation.²⁸ Its advantages include short examination time, wide availability, fracture detection, paucity of contraindications, and high accuracy. Although MRI is more sensitive in detecting intracranial injuries, its use is limited by longer examination times, the need for sedation in uncooperative patients, and difficulties in monitoring potentially hemodynamically unstable patients. Once patients have been stabilized, MRI becomes the modality of choice for fully elucidating the nature and extent of injury.²⁹

Traumatic brain injury (TBI) may result in contusion, axonal (shear) injury, or hematoma. Larger contusions may contain petechial microhemorrhages and appear as ill-defined heterogeneous lesions with little or no mass effect. As edema and mass effect increase in the first 48 hours, lesions become more evident.

Shear injuries are most common within the white matter. Except for location, the imaging characteristics of nonhemorrhagic contusions and shear injuries are similar. Initial studies may be normal or demonstrate small foci of edema. Shear injuries may be apparent on MRI, particularly with the use of (1) SWI, which is exquisitely sensitive to the microhemorrhages; (2) DWI, which may show cytotoxic edema; and (3) MRS, which may show choline (Cho) and myoinositol (mI) elevations and decreases in *N*-acetylaspartate (NAA) proportional to injury severity.

TBI may also lead to hemorrhage into the epidural, subdural, and subarachnoid spaces. On CT, intraventricular and subarachnoid hem-

orrhage is identified by replacement of the normal low-density CSF by high-density blood. When subtle, a subarachnoid hemorrhage can be mistaken for generalized edema, with loss of the basal cisterns and cortical sulci. Subdural hematomas appear as crescentic mixed or hyperdense collections that cross suture lines but not dural attachments (Fig. 58-5A). Epidural hematomas appear as biconvex hyperdense collections that cross dural attachments but not suture lines (Fig. 58-5B). With rapid accumulation of blood, an unretracted, semiliquid clot may be present. In this situation, CT demonstrates hypodense areas within the hyperdense hematoma (swirl sign).³⁰ Distinction between epidural and subdural hematomas is important, because

FIGURE 58-2 ■ Cytotoxic edema and acute infarct. Axial non-contrast-enhanced computed tomography scan demonstrates an area of decreased density (asterisk) involving the left middle cerebral artery territory. Gray and white matter structures are involved, and there is little mass effect.

FIGURE 58-4 ■ Right descending transtentorial herniation in patient with large right parietal subdural hematoma. Axial non-contrast-enhanced computed tomography scan of head at level of mid-brain shows that ipsilateral subarachnoid cistern is widened (arrow), and contralateral subarachnoid cistern is obliterated because of brainstem rotation. Left temporal horn is also dilated (asterisk), indicating trapping of left lateral ventricle.

FIGURE 58-3 ■ Hemorrhage. Axial computed tomography image (A) demonstrates a large area of acute hemorrhage (H) in right temporal lobe. T1-weighted (B) and T2-weighted (C) magnetic resonance imaging scans demonstrate the hemorrhage in various stages of breakdown. Center of lesion is dark on T1- and T2-weighted images, indicating oxyhemoglobin (1). Intermediate zone is bright on T1-weighted image and gray on T2-weighted image, indicating intracellular methemoglobin (2). Outer rim is bright on both T1- and T2-weighted images, indicating extracellular methemoglobin (3).

TABLE 58-1

Evolution of Computed Tomography and Magnetic Resonance Imaging Appearance of Hemorrhage

| STAGE | TIME PERIOD | BLOOD PRODUCT | CT* | T1WI† | T2WI† |
|----------------|-------------|-----------------------------|--------|--------|-------|
| Hyperacute | <12 hours | Oxyhemoglobin | ↔ or ↑ | ↓ or ↔ | ↑ |
| Acute | 1-3 days | Deoxyhemoglobin | ↑ | ↓ or ↔ | ↓↓ |
| Early subacute | 3-14 days | Intracellular methemoglobin | ↔ | ↑ | ↓↓ |
| Late subacute | 2-4 weeks | Extracellular methemoglobin | ↔ | ↑↑ | ↑ |
| Chronic | >2 weeks | Hemosiderin | ↓ | ↔ | ↓↓ |
| | | Nonparamagnetic hemichromes | ↓ | ↓ | ↑ |
| | | Calcification | ↑↑ | ↓ | ↓ |

*Density relative to brain parenchyma

†Intensity relative to brain parenchyma

FIGURE 58-5 ■ Subdural and epidural hematoma. **A**, Axial computed tomography (CT) scan of head demonstrates a mixed-density subdural hematoma along the right frontoparietal lobes. Mixed-density appearance is most likely due to presence of unretracted semiliquid clot. **B**, Axial CT scan of head demonstrates a left biconvex hyperdense collection that is classic for epidural hematoma. A fracture (arrow) can also be identified.

epidural hematomas often have an arterial source, expand rapidly, and require emergent drainage.³¹

Abusive head trauma (AHT) is a significant cause of neurodevelopmental morbidity and mortality in children less than 2 years old.³² Injuries commonly encountered include skull fractures, subdural hematomas, subarachnoid hemorrhages, and shear injuries. Subdural hematomas in young children are more often associated with AHT than with accidental trauma.³² MRI can estimate the age of a hemorrhage; coexistence of blood products of different ages (Fig. 58-6) suggests recurrent bleeding from repeated abuse, although this finding must be interpreted with caution.⁷

Vascular Lesions

Ischemia, Hypoxia, and Infarction. CT reveals only about half of ischemic infarcts within the first 48 hours but is frequently used to exclude a hemorrhagic etiology. Features on CT can identify patients who are at a higher risk of hemorrhagic transformation.³³ CT can suggest a thromboembolic etiology for ischemia by showing cerebral edema in a vascular distribution or by showing a hyperdense clot within a thrombosed artery. CT can also show mass lesions (e.g., malignant cerebral edema) that require emergency surgical treatment.⁵ Small lacunar infarcts and infratentorial strokes are difficult to visualize by CT.³⁴

FIGURE 58-6 ■ Abusive head trauma. Axial T1- (**A**) and T2-weighted (**B**) magnetic resonance imaging scans of an infant reveal bilateral subdural blood collections of different ages. Right collection shows blood in the late subacute phase (2-4 weeks old), and left shows blood in the chronic phase (>1 month). This finding is highly suggestive of repeated abuse.

In the hyperacute stage (first 24 hours), an infarcted area may appear normal on CT or show a subtle loss of density and gray-white differentiation (Fig. 58-7). During the acute stage (first week), the infarct shows mass effect and decreased density from cytotoxic edema (see Fig. 58-2). In the subacute stage (second to third weeks), the edema and mass effect gradually resolve. Chronic infarcts demonstrate parenchymal replacement and contraction, with sharply margined zones of cystic encephalomalacia and gliosis.

The MRI appearance of an ischemic infarct also evolves (Fig. 58-8). Nonhemorrhagic infarcts begin with subtly increased signal intensity

on T2WI and minimal changes on T1WI. Subtle findings include stagnation of blood flow (arterial enhancement) and swelling of the involved gyri. DWI (Fig. 58-9) can show cytotoxic edema minutes after an infarct occurs, but the intensity is typically maximal at 3 to 5 days and fades over 1 to 2 weeks. Because cytotoxic edema and T2 hyperintense lesions both appear bright on DWI (T2 shine-through), cytotoxic edema is best evaluated using the apparent diffusion coefficient (ADC) map, on which cytotoxic edema appears hypointense.

CT and MRI perfusion techniques can demonstrate diminished perfusion within minutes of an insult. When MRI perfusion studies

FIGURE 58-7 ■ Acute infarct. Axial non-contrast-enhanced computed tomography (CT) images obtained at level of temporal lobe (A) and through level of basal ganglia (B) demonstrate area of low density involving gray and white matter of right hemisphere. There is loss of gray-white matter differentiation, especially noticeable in region of basal ganglia (asterisk, B). Compare right and left sides. High density is identified within right middle cerebral artery (arrow, A), representing clot. Axial non-contrast-enhanced CT scan obtained 48 hours later (C) demonstrates marked edema involving territories of right, middle, and posterior cerebral arteries. Note sparing of right anterior cerebral artery territory (asterisk, C).

FIGURE 58-8 ■ Infarct. Axial T1-weighted (A) and T2-weighted (B) magnetic resonance imaging (MRI) scans of patient being evaluated for stroke. Initial computed tomography scan (not shown) was normal. Magnetic resonance imaging demonstrates an area of cytotoxic edema involving distal left middle cerebral artery territory. Edema is hypointense to brain on T1-weighted image and hyperintense to brain on T2-weighted image. Left internal carotid artery angiogram (C) demonstrates occluded branch of left middle cerebral artery (arrow). Within the proper time frame, intraarterial thrombolysis would be a method of management for this patient.

FIGURE 58-9 ■ Hyperacute infarct. Axial T1-weighted image before (A) and after (B) contrast administration reveal subtle low-intensity and arterial enhancement (arrow) in right insular cortex. Fluid-attenuated inversion recovery (FLAIR) sequence (C) helps define area of involvement. Diffusion-weighted sequence (D) shows infarct most clearly. Acute phase is confirmed by low signal on apparent diffusion coefficient map (E).

FIGURE 58-10 ■ Perfusion deficit. Magnetic resonance imaging perfusion study shows hypoperfusion in the territory of the left middle cerebral artery after thromboembolic obstruction at the M1 segment.

are coupled with diffusion images, a penumbra can be identified as a zone of viable but hypoperfused tissue (Fig. 58-10).⁹

Imaging protocols using several MRI sequences for acute evaluation of a suspected stroke can provide information about anatomy, presence of blood, extent of infarction, vascular anatomy, blood flow, and metabolic alterations (see Fig. 58-10).³⁵

MRI findings in hypertensive encephalopathy include symmetric vasogenic edema in the subcortical white matter, primarily in the occipital and parietal lobes. Radiologically similar lesions, referred to as *posterior reversible encephalopathy syndrome* (PRES), have been seen in association with hypertension but also with a number of other conditions. Most perfusion studies have been consistent with decreased blood flow.³⁶ In up to 25% of cases, cytotoxic edema and hemorrhage are also seen.^{37,38}

In contrast to arterial infarctions, venous infarctions are typically hemorrhagic and primarily affect the white matter. CT and MRI are able to detect the hemorrhage and edema as well as venous sinus thrombosis. Venography can be helpful in fully characterizing and following an occlusion.

The brain of a term infant has its greatest myelination and metabolic activity in the brainstem, basal ganglia, cerebellum, and periorbital cortex. Global hypoxic-ischemic injuries in term neonates are

most commonly seen in these regions.³⁹ The full extent of an ischemic injury may not be apparent on MRI in the first 72 hours because of ongoing neuronal apoptosis. Within a year, the patterns of injury seen from vascular insults become similar to those seen in older children and adults, with selective vulnerability in the striatum, lateral geniculate bodies, hippocampi, and frontal and parieto-occipital cortex, with sparing in moderate injuries of the thalami and perirolandic cortex (Fig. 58-11).³⁸ The relative sparing of the cerebellum, even with severe global hypoxic-ischemic injury of the cerebral hemispheres, can result in a “cerebellar reversal” sign on CT.⁴⁰

FIGURE 58-11 ■ Global anoxic injury. Axial computed tomography scan of a child following cardiac arrest. There is diffuse low density in cerebral hemispheres and compression of ventricles and sulci, reflecting increased water accumulation (edema) and resultant mass effect. Basal ganglia and thalami appear bright.

Congenital Aneurysm and Subarachnoid Hemorrhage. Evaluation of suspected subarachnoid hemorrhage usually begins with a non-contrast head CT (Fig. 58-12). If subarachnoid blood is seen on CT or lumbar puncture, a conventional angiographic study can be done to look for cerebral aneurysms (see Fig. 58-12). MRA and CTA are insufficiently sensitive to exclude an aneurysmal source of bleeding.⁴¹ Conventional angiography provides the superior anatomic detail needed for planning treatment.

From 10% to 30% of patients with aneurysmal subarachnoid hemorrhage will develop a delayed ischemic neurologic deficit from vasospasm.⁴² Angiographic studies show vasospasm but do not clearly differentiate between symptomatic and asymptomatic narrowing. Treatments for patients with symptomatic vasospasm show promise.^{43–45}

Vascular Malformations. AVMs are the most common vascular malformation. An unruptured AVM may be apparent on CT as tubular structures that enhance with contrast. On MRI, the abnormal vessels may appear hypointense because of blood flow. Conventional angiography is preferred for the evaluation of suspected AVMs, as it is best able to differentiate them from arteriovenous fistulas, identify associated aneurysms, and assess the feeding arteries and draining veins (Fig. 58-13).⁴⁶ An interventional radiologist may be able to embolize some or all of the arterial feeders, making surgery either less complex or unnecessary.⁴⁷ Capillary telangiectasias and cavernous angiomas are best evaluated by MRI because angiography is typically normal and CT is insensitive. The MRI signal characteristics vary based on the presence or absence of associated hemorrhage.

Developmental venous anomalies (DVA) are composed of a large draining vein surrounded by small feeding veins. The veins are typically inapparent on non-contrast-enhanced CT but enhance with contrast and can be seen on conventional MRI as flow voids. DVAs are rarely symptomatic other than when associated with a cavernous angioma or AVM, and conventional angiography is recommended only when an apparently simple DVA is associated with unexplained hemorrhage or edema.⁴⁸

Neoplasia

On CT, low-grade gliomas may appear as subtle nonenhancing masses, but higher-grade gliomas with large areas of necrosis and vasogenic edema often demonstrate heterogeneous enhancement (Fig. 58-1).

FIGURE 58-12 ■ Subarachnoid hemorrhage and aneurysm. **A**, Axial non-contrast-enhanced computed tomography scan of head reveals high density (blood) replacing normal low density of cerebrospinal fluid within suprasellar cistern and subarachnoid spaces, indicating subarachnoid hemorrhage. Also note dilated temporal horns (arrows), indicating acute hydrocephalus. **B**, Right internal carotid artery angiogram demonstrates presence of congenital anterior communicating artery aneurysm (arrow), as well as vasospasm (curved arrows).

FIGURE 58-13 ■ Arteriovenous malformation. **A**, Axial non-contrast-enhanced computed tomography (CT) scan of head reveals a vague area of hyperdensity in posterior left parietal region. **B**, Contrast-enhanced CT scan demonstrates serpiginous enhancement of this lesion (arrow). **C**, Internal carotid artery angiogram demonstrates arteriovenous malformation being fed by middle cerebral artery.

FIGURE 58-14 ■ Intracranial metastatic disease. Axial contrast-enhanced computed tomography scan of head reveals multiple enhancing nodules throughout gray and white matter structures, consistent with metastatic disease.

Metastatic lesions may be low-density-enhancing masses, or they may have high density secondary to hemorrhagic components (Fig. 58-14). Cystic tumors may have the density of CSF (Fig. 58-15). Epidermoid and dermoid tumors frequently contain areas of fat density that appear hypodense to CSF.

MRI has high sensitivity but low specificity in the evaluation of neoplasms. Tumors are typically of low intensity on T1WI and high intensity on T2WI (see Fig. 58-1). DWI and MRS are helpful in pre-surgical staging and grading, selection of biopsy sites, and monitoring response to therapy.^{15,49} DTI and fMRI can show the relationship between a tumor and eloquent cortex and critical white matter tracts, defining and minimizing the risks of resection.⁵⁰ MRS, DWI, and PET can distinguish postradiation necrosis from tumor recurrence.^{10,51}

Infection and Inflammation

CT and MRI may initially appear normal in encephalitis but later show areas of cortical edema or hemorrhage. DWI can show areas of diffusion restriction early in the disease.⁶ The herpes simplex virus (HSV) shows a strong predilection for the temporal, insular, and cingulate regions in older children and adults but less specificity in neonates.⁵² Acute disseminated encephalomyelitis (ADEM) is an immune-mediated, often postinfectious encephalitis that usually

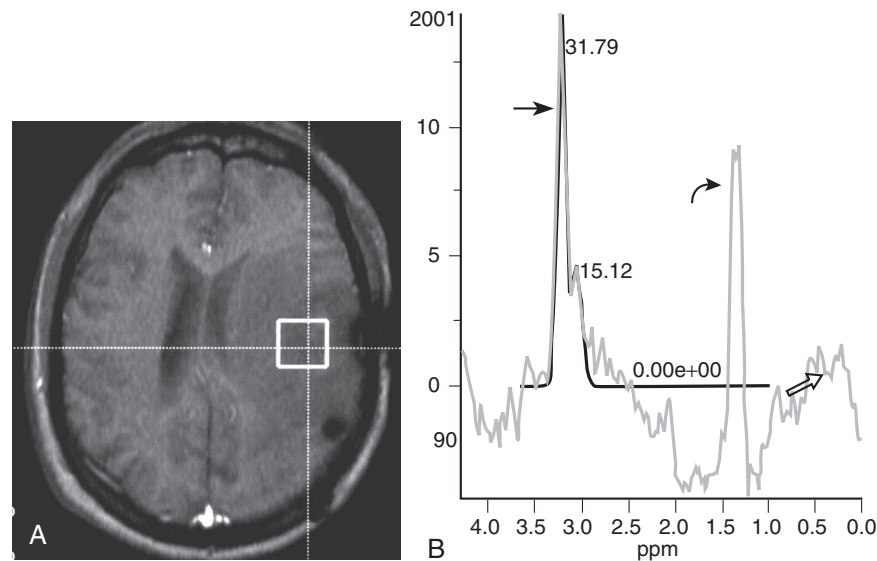

FIGURE 58-15 ■ Recurrent high-grade astrocytoma. Study performed after radiation therapy (not shown) showed increased edema and mass effect; differential diagnosis included recurrent tumor and radiation necrosis. **A**, Axial magnetic resonance imaging scan shows volume of tissue (box) selected for spectroscopy. **B**, Proton spectroscopy reveals increase in choline peak (arrow), decrease in *N*-acetyl aspartate peak (curved arrow), and appearance of a lactate peak (open arrow). This appearance is consistent with recurrent tumor, which was verified by repeat surgery and biopsy.

appears as symmetric demyelination and edema in the subcortical white matter.⁵³

On CT, an abscess cavity demonstrates central hypodensity, a thin, isodense wall that enhances with IV contrast, and surrounding low-density edema. On MRI, the central cavity varies in intensity but the capsule is typically iso- to hyperintense on T1WI, hypointense on T2WI, and enhances with contrast. DWI and MRS can be useful in distinguishing an abscess from other cystic lesions.⁶

In meningitis, CT and MRI may be normal or demonstrate diffuse meningeal contrast enhancement. Ventriculitis shows contrast enhancement of the involved ventricular walls. On CT, subdural and epidural empyemas most often have a density intermediate between CSF and acute blood. On MRI, these pyogenic collections are hypointense to brain on T1WI and hyperintense on T2WI.

White Matter and Metabolic Diseases

MRI is preferable to CT for determining the presence and extent of white matter disease (Fig. 58-16). Lesions appear hypointense on T1WI and hyperintense on standard T2WI; subependymal lesions are more conspicuous on FLAIR.

Most white matter diseases are slowly progressive, but acute presentations occur with toxic and vascular insults.⁵⁴ Carbon monoxide poisoning causes selective injury to the putamina, thalami, caudate heads, cerebellum, and cerebral white matter.⁵⁵ With Wernicke encephalopathy, MRI can show selective injury to the thalami, hypothalamus, periaqueductal dorsal midbrain, mammillary bodies, and medullary tectum.⁵⁶ Methanol ingestion can cause hemorrhagic necrosis of the caudate heads, putamina, pons, optic nerves, and subcortical white matter.⁵⁷

Immunosuppressive medications have been associated with PRES, and several chemotherapeutics, particularly intrathecal methotrexate, can cause toxic demyelination.¹⁰ Osmotic myelinolysis due to rapid correction of hyposmolality may affect the central pons but sometimes involves the thalami, basal ganglia, and deep white matter.⁵⁸

Encephalopathy due to liver disease can appear as T1WI hyperintensity in the globus pallidi, subthalamic nuclei, and midbrain; T2WI hyperintensity in the cortex; and MRS evidence of decreased Cho and mI and increased glutamine and glutamate.⁵⁹

SPINAL CORD

Patterns of Disease

Spinal cord pathology can be classified according to location (Fig. 58-17), usually requiring MRI.⁶⁰ With acute trauma, however, initial bony alignment and stability are better assessed by plain radiography and CT.

Intraductal lesions expand the spinal cord, compressing the subarachnoid space (Fig. 58-17, A), and are usually neoplastic, presenting with slowly progressive symptoms.

Extraductal-intradural lesions displace the arachnoid layer of the meninges but leave the dura in place such that the subarachnoid CSF flares out to form a “cap” at its interface with the lesion (Fig. 58-17, B). Meningiomas, nerve sheath tumors, and other benign tumors account for most lesions in this space.⁶¹

Extradural lesions usually displace the subarachnoid space and spinal cord (Fig. 58-17, C). Excluding disk disease, the most common extradural pathology is metastatic disease.

Specific Disease Processes

Spinal Cord Injury

Plain x-rays are able to identify most unstable injuries. However, some vertebral fractures and misalignments will be missed (Fig. 58-18, A). CT with axial, coronal, and sagittal reconstructions should be considered whenever fractures are seen or suspected (Fig. 58-18, B and C).⁶²

MRI is recommended when the patient has neurologic deficits, an unstable injury by previous imaging, or symptoms of an unstable injury despite a normal CT⁶³ but may be unnecessary in most obtunded

FIGURE 58-16 ■ Progressive multifocal leukoencephalopathy. Axial T2-weighted (A) and fluid-attenuated inversion recovery (FLAIR) (B) images in patient with human immunodeficiency virus (HIV). Multiple areas of white matter disease are identified; FLAIR image clarifies the involvement of periventricular white matter. These findings in an HIV-positive patient strongly suggest progressive multifocal leukoencephalopathy.

FIGURE 58-17 ■ Spinal compartments. Anteroposterior (AP) and lateral (LAT) views of spinal cord and canal demonstrate appearance of an intramedullary lesion (A), extramedullary intradural lesion (B), and extradural lesion (C).

and comatose trauma patients.⁶⁴ MRI can directly visualize intrinsic spinal cord and soft tissue injuries and can distinguish between hemorrhagic (poorer prognosis) and edematous cord injuries. A disk herniation with cord compression can change management from nonsurgical to surgical or change the surgical approach. MRI is also useful in detecting ligamentous injuries and the extent to which hematomas or bony displacements compress the spinal cord or nerve roots (Fig. 58-18, D).

Spinal Infection

MRI has a higher sensitivity than plain films and CT for spinal infections.⁶⁵ In spondylitis, MRI findings include narrowing of the disk space, contrast enhancement, hypointensity on T1WI in the vertebral bodies, and hyperintensity on T2WI in the vertebral bodies and disk (Fig. 58-19). Skip lesions and associated large paraspinal abscesses suggest mycobacterial infection. Nuclear medicine studies may help identify chronic spondylitis or surgical hardware infection.⁶⁶ In myelitis, typical MRI findings are focal or diffuse areas of T2WI hyperintensity with variable contrast enhancement.⁶⁷

Neoplasia

MRI is the primary modality for the evaluation of suspected spinal and paraspinal tumors.⁶⁸

The spinal column is the third most common site for tumor metastasis. Plain radiographs can show the “moth-eaten” outline of diffuse vertebral body cortical destruction. Vertebral collapse is more likely caused by neoplasia than degenerative disease when there is unilateral bone destruction, irregular or angular distortion of the vertebral endplates, involvement of the upper thoracic spine, a soft tissue mass, or pedicle destruction.⁶⁹ The bone marrow of vertebral bodies with neoplastic infiltration appears hypointense on T1WI and hyperintense on T2WI (Fig. 58-20). The bone marrow of vertebrae with benign fractures shows normal imaging characteristics (Fig. 58-21).

ACKNOWLEDGMENTS

Portions of this chapter appeared in a previous edition of this book authored by Dr. Fred J. Laine.

FIGURE 58-18 ■ Posttraumatic vertebral body compression fracture. Lateral plain film (**A**) of thoracolumbar junction reveals a compression fracture involving L1 vertebral body (*asterisk*). Decreased height of vertebral body and inferior anterior corner fracture are well seen. Retropulsed body can also be seen when outline of adjacent vertebral bodies (*lines*) are compared. Axial (**B**) and sagittal reconstructed (**C**) computed tomography scans of same patient add substantial detail to degree of canal narrowing secondary to retropulsed fragment. Left lamina fracture (*arrow*, **B**) is also seen—not apparent on the plain film. **D**, Sagittal T2-weighted magnetic resonance imaging demonstrates compression fracture of L1 and retropulsed posterior body, as well as contusion and swelling of conus (*arrows*) as a direct result of compression fracture.

FIGURE 58-19 ■ Discitis with epidural abscess. Sagittal postcontrast T1-weighted (**A**) and T2-weighted (**B**) magnetic resonance imaging scans demonstrate features of discitis and adjacent osteomyelitis. Vertebral bodies and disc space are of low signal intensity on T1-weighted image and of bright signal intensity on T2-weighted image (*straight arrows*). Epidural abscess surrounding and compressing cord is also identified (*curved arrow*).

FIGURE 58-20 ■ Metastatic disease. Sagittal T1-weighted (**A**) and T2-weighted (**B**) magnetic resonance imaging scans of spine show metastatic lesions (*arrows*) as low intensity on T1-weighted image, replacing normal bright marrow. High signal within uninvolved vertebral bodies represents postradiation changes. Hypointense lesions on T2-weighted image (in contrast to more typical hyperintensity) reflect posttreatment appearance. Multiple compression fractures are identified within upper thoracic spine, with collapse, retropulsed fragments, and cord compression. Edematous changes within cord secondary to compression (*asterisk*) are also identified.

FIGURE 58-21 ■ Benign compression fracture. Sagittal T1-weighted (A) and T2-weighted (B) magnetic resonance imaging scans demonstrate compression fracture of L5. Compare signal characteristics of remaining bony elements and pedicles with signal of normal bony structures.

KEY POINTS

Methods

1. CT can be acquired quickly with few contraindications. MRI provides greater detail and uses no ionizing radiation but requires more time to acquire.

Brain

1. CT and MRI help differentiate lesions of different etiologies.
2. Infarctions and hemorrhages change in appearance over time.
3. CT is useful for acutely evaluating SAH, obstructive hydrocephalus, and mass lesions.
4. CT can exclude hemorrhage in patients with suspected infarction.
5. Multiple imaging modalities are useful for evaluating CNS tumors.

Spine

1. CT can identify unstable spinal trauma requiring surgical intervention. MRI is more sensitive for soft tissue and spinal cord injuries.
2. MRI is preferable for evaluating diseases affecting the spinal cord.

Appropriate neurocritical care is fundamental to the success of neurosurgical interventions involving the brain and spinal cord. Great technical advances in operative procedures have made lesions previously considered inoperable now treatable, and advances in anesthesia have led to an increased number of operative procedures in both elderly and critically ill patients. Consequently, the number of patients requiring postoperative intensive care has increased.

Successful care of the neurosurgical patient requires close collaboration between various specialists: neurosurgeons, anesthesiologists, intensivists, and neuroradiologists. The results of a technically perfect operation can be ruined by inadequate postoperative care, while a complex operative procedure requires expert intensive care to correct abnormalities in homeostatic mechanisms, ensure adequate cerebral perfusion and oxygenation, and promote recovery of brain function. The complex interaction between the central nervous system (CNS) and systemic functioning requires detailed knowledge of both general intensive care and cerebral and spinal pathophysiology. Anticipation and early response prior to the full-blown development of complications are hallmarks of good neurocritical care. For example, when serum sodium levels are decreasing, correction should be implemented before hyponatremia develops, as hyponatremia may lead to increased brain edema. The best care for neurosurgical patients can be provided by dedicated specialists with knowledge of both fields and a large amount of experience in treating such patients.

The benefit of concentration of care in hospitals and units with sufficient case volume has been well established in different fields of intensive care medicine, including trauma,¹ neonatology, and specifically neurointensive care.²⁻⁸

Treatment of patients with spontaneous intracerebral hemorrhage in a dedicated neurointensive care unit (neuro-ICU) is associated with reduced mortality, when compared with patients admitted to a general intensive care unit (ICU),^{9,10} and mortality following aneurysmal subarachnoid hemorrhage (SAH) is lower in centers with a higher case volume.^{5,11} Patel and colleagues¹² unequivocally showed a 2.15 times increase in the odds of death (adjusted for case mix) for patients with severe traumatic brain injury (TBI) treated in nonneurosurgical centers versus neurosurgical centers. Their report makes a strong case for transferring all patients with severe TBI to a setting with 24-hour neurosurgical and neurocritical care facilities. A subsequent study demonstrated that transfer of nonsurgical patients with TBI to neuroscience centers resulted in substantial improvements in the risk-adjusted odds ratio for mortality (0.52; confidence interval [ci], 0.34-0.80).¹³ Protocol-driven approaches in adult and pediatric intensive care, as well as treatment in centers with higher patient volumes, are associated with better outcome.¹³⁻¹⁷

The admission policy for postoperative neurosurgical care in ICUs varies widely among countries and centers and even within centers. In some centers, all patients who have undergone intracranial procedures are admitted for a 24-hour observation period following surgery; this is motivated by the observation that some patients, although fully alert and neurologically intact initially, may subsequently develop complications necessitating prompt intervention.

In other centers, patients are only admitted to the ICU after intracranial complications have been detected. Some hospitals have dedicated neuro-ICUs, and in others, patients are admitted to a general ICU, sometimes even to different ICUs within one hospital. In general, the

scarcity of ICU beds has also led to a more restrictive admission policy for postoperative neurosurgical care. The institution of high-care units, sometimes termed “step-down units”, may permit more efficient use of scarce intensive care resources, while at the same time affording sufficient guarantees for adequate postoperative monitoring. Here again, however, care should be provided by personnel well experienced in the care of such patients, thus permitting early detection of possible deterioration and prevention of secondary complications.

PRIORITIES AND GOALS OF POSTOPERATIVE NEUROSURGICAL CARE

The principal goal of postoperative neurosurgical intensive care is early detection and treatment of postsurgical complications. The second goal is to prevent second insults that may initiate or exacerbate secondary damage in a vulnerable CNS.

Consequently, priorities are to ensure adequate monitoring facilities, which may in the sedated and ventilated patient require further invasive monitoring of the intracranial system, and to ensure adequate oxygenation and perfusion of the brain. Postoperative complications may be systemic or neurosurgical (Table 59-1).

PREVENTION AND MANAGEMENT OF SYSTEMIC COMPLICATIONS AFTER NEUROSURGERY

General Principles and Second Insults

The prevention and management of systemic complications after neurosurgical procedures follow general principles of “intensive care” medicine. Systemic complications and second insults may initiate or aggravate cerebral damage. Aggressive treatment aimed at preventing and limiting second insults is of paramount importance. The main second insults, along with their causes and adverse effects on brain homeostasis and function, are summarized in Table 59-2. This table illustrates the complex interactions between systemic events and CNS function.

Conversely, CNS events may induce systemic derangements. For example, in response to raised intracranial pressure (ICP), mean arterial blood pressure (MABP) may increase as a compensatory mechanism to ensure adequate cerebral perfusion (Cushing response). In such situations, treatment of hypertension is contraindicated, as this may exacerbate cerebral ischemia. In other situations, however, arterial hypertension may aggravate the occurrence of cerebral edema and/or increase the risk of intracranial bleeding. Surgeons may request preventing any episode of high blood pressure (BP) in situations where adequate hemostasis was difficult, or conversely, they may wish to maintain BP at relatively high levels when cerebral vasospasm may be a problem, such as after cerebral aneurysm surgery. The clinical dilemma is to balance the desire of limiting edema formation and the risk of postoperative hemorrhage with the goal of maintaining adequate perfusion. Knowledge of the operative findings and close interaction with the surgeon are of paramount importance.

TABLE 59-1 Postoperative Complications

| SYSTEMIC COMPLICATIONS | NEUROSURGICAL COMPLICATIONS |
|--|--|
| <ul style="list-style-type: none"> Coagulation disorders: blood loss, disseminated intravascular coagulation, drug induced Thromboembolic: DVT, pulmonary embolism, myocardial infarction Pulmonary: atelectasis, pneumothorax, ventilator-associated pneumonia Hypovolemia: insufficient pre- and perioperative hydration, blood loss Infection: pneumonia, urinary tract infection, catheter sepsis Metabolic: hyperglycemia (steroid-induced), diabetes insipidus, hyponatremia Air embolism: sitting position, opening of large cerebral veins during surgery Pressure sores and decubitus ulcers: intraoperative positioning, cervical traction, paraplegia | <ul style="list-style-type: none"> Postoperative hematoma: subgaleal, epidural, subdural, intraparenchymal Cerebral ischemia: subarachnoid hemorrhage, vasospasm, vessel occlusion Brain swelling: edema, vasodilation Infection: meningitis, subdural empyema, cerebral abscess Seizures: infection, depressed compound skull fracture, cortical lesions Hydrocephalus: obstruction/resorption Tension pneumocephalus CSF fistula Inverse cerebellar herniation Cranial nerve lesions |

CSF, cerebrospinal fluid; DVT, deep venous thrombosis.

Many drugs routinely used in neurosurgical patients (e.g., steroids, antiepileptic agents) may cause complications or side effects. Awareness of these potential side effects is essential. CNS damage, particularly to the hypothalamus region, brainstem, and cervical spinal cord, may lead to disturbances in temperature control, causing hypo- or hyperthermia. In patients with spinal cord injury, loss of autonomic sympathetic function may further lead to peripheral vasodilation and low BP. In the absence of beta-blocking agents, hypotension in combination with bradycardia is strongly suggestive of damage to the spinal cord.

Cardiac Dysfunction

Electrocardiographic abnormalities, usually ST-segment changes mimicking cardiac ischemia and cardiac arrhythmias, may be caused by SAH, TBI, or raised ICP. Cardiac complications in the acute phase of SAH are well known.¹⁸ The left ventricle suffers a typical bulging (indicating ischemic changes and functional impairment), which has been awarded the term *takotsubo syndrome*, with reference to the shape of a pot used by ancient Japanese fishermen for catching octopus. The extent of left ventricular dysfunction is variable, but it may lead to cardiac failure and pulmonary edema.^{19,20} A 2014 study reported echocardiographic abnormalities in 22.3% and a reduced left ventricular ejection fraction in 12% of patients with isolated TBI.²¹

Neurogenic Pulmonary Edema

The development of neurogenic pulmonary edema has been described early in the postoperative period after a variety of neurosurgical procedures, including brain tumors (particularly those resected in the posterior fossa), cysts, hydrocephalus, intracranial hemorrhages, and brainstem lesions.²²⁻²⁵ Although an infrequent event, neurogenic pulmonary edema is potentially life-threatening and requires rapid evaluation and emergent therapy in the ICU.²⁵ A 9% mortality rate directly attributable to neurogenic pulmonary edema has been reported in a review of this condition. Generally, this complication appears in the initial 4 hours after the neurologic event and is more common in women than in men, possibly related to the preponderance of cases in

TABLE 59-2 Systemic Second Insults

| EVENT | MAIN CAUSES | ADVERSE EFFECT |
|---------------|--|--|
| Hypoxemia | Hypoventilation Aspiration atelectasis Pneumothorax Pneumonia Anemia | Decreased oxygen delivery and increased risk of ischemic damage |
| Hypotension | Hypovolemia Cardiac failure Sepsis, spinal cord injury | Decreased CPP, decreased CBF, increased risk of ischemia |
| Anemia | Blood loss | Decrease in oxygen transport and delivery, increased risk of ischemic damage |
| Hypercapnia | Respiratory depression | Increased cerebral blood volume, raised ICP |
| Hypocapnia | Hyperventilation (spontaneous or induced) | Cerebral vasoconstriction with increased risk of ischemic damage |
| Hyperthermia | Hypermetabolism, stress response, infection Central dysregulation | Metabolic requirements may exceed substrate delivery, resulting in energy depletion |
| Hypothermia | Exposure, central dysregulation | May be neuroprotective but can cause significant coagulopathy and electrolyte disturbances |
| Hyperglycemia | IV infusion of dextrose, steroids, stress response | Acidosis, electrolyte disturbances |
| Hypoglycemia | Inadequate nutrition, insulin overdose, pituitary insufficiency | Energy depletion in the brain, seizures |
| Hyponatremia | Inadequate salt intake (hypotonic fluids) Excessive sodium loss (cerebral salt wasting/CSF drainage) Syndrome of inappropriate ADH | Increased edema, seizures |
| Hypernatremia | Diabetes insipidus Osmotic agents (mannitol, hypertonic saline) | Lethargy, coma |

ADH, antidiuretic hormone; CBF, cerebral blood flow; CPP, cerebral perfusion pressure; CSF, cerebrospinal fluid; ICP, intracranial pressure; IV, intravenous.

patients with SAH.²⁵ The mechanisms underlying this condition are unclear; a sudden central sympathetic discharge may trigger pulmonary vasoconstriction, systemic arterial hypertension, increased left ventricle afterload, and increased capillary permeability in the pulmonary vascular bed and simultaneously cause cardiac ischemia and ventricular failure.^{20,26} Because of these multiple mechanisms, neurogenic pulmonary edema can be interpreted as noncardiogenic or, at least in part, as cardiogenic.²⁷ Both low- and high-protein content has been reported in the edema fluid.^{25,28} It is commonly associated with raised ICP, and, in addition to therapies directed at intracranial hypertension, therapeutic measures are mostly supportive. To attenuate the massive sympathetic discharge, opioids and sedatives are used. Supplemental oxygen is uniformly required, and tracheal intubation with mechanical ventilation and the application of positive end-expiratory pressure have been reported in about 75% of patients.²⁵ Diuretics have been used, provided that volume status is adequate, but they are less effective than in cardiac edema. Most patients require vasoactive drugs.²⁸

Hypercoagulopathy and Thrombosis Prophylaxis

Release of factors from damaged brain tissue may induce local and systemic hypercoagulopathy.²⁹⁻³¹ Various studies have confirmed a transient hypercoagulopathy syndrome both in the immediate postoperative phase after brain surgery and in patients with TBI.^{29,32,33,34} In patients with a subdural hematoma, consumption of clotting factors may lead to coagulopathy in up to 22% of patients.³⁵ The current hypothesis for the development of coagulopathy in brain injury implicates a combination of both hypo- and hypercoagulable states, triggered by damaged brain tissue, and resulting in secondary injury via subsequent ischemic or hemorrhagic lesions. The proposed underlying mechanisms include the release of tissue factor, hyperfibrinolysis, and, more specifically in trauma patients, hypoperfusion (with triggering of the protein C pathway) and the development of disseminated intravascular coagulation.^{36,37}

Deep venous thrombosis (DVT) has been reported to occur in 18% to 50% of neurosurgical cases³⁸ and pulmonary embolism (PE) in 0% to 25%. The incidences of DVT and PE are particularly high in brain tumor patients. Nevertheless, neurosurgeons tend to underestimate the risk of DVT and PE³⁹ and are sometimes reluctant to routinely prescribe anticoagulant prophylaxis for fear of increasing the risk of postoperative bleeding.⁴⁰ Options for prevention of thrombosis prophylaxis in neurosurgical patients include both mechanical (e.g., graduated compression stockings, intermittent pneumatic compression stockings), and pharmacologic (e.g., low dose of classic heparin, low-molecular-weight heparin) therapies. Intuitively, mechanical therapies carry less associated risk, but pharmacologic approaches are more effective in preventing thrombotic complications. Various studies have indeed shown a higher incidence of postoperative hemorrhagic complications,⁴¹ but not all are clinically relevant.

Overall, existing evidence, however, shows that the beneficial effects in reducing DVT, and in particular PE^{42,43} outweigh a slightly increased risk of clinically significant hemorrhagic complications with anticoagulant prophylaxis. These data support the administration of antithrombotic prophylaxis to patients undergoing neurosurgical procedures,⁴⁴ including those with intracranial hemorrhagic lesions⁴⁵ or closed TBI,^{46,47} as well as high-risk trauma patients.^{48,49} Practice recommendations from the Trauma Quality Improvement program of the American College of Surgeons advise initiation of venous thromboembolism prophylaxis within the first 72 hours after TBI in most patients (<https://www.facs.org/quality-programs/trauma/tqip>). However, opinions differ, and careful estimation of the balance of benefits versus risk should be sought, informed by objective assessments of coagulation status.⁵⁰⁻⁵³ It has been recommended that removal of catheters or drainage tubes in the postoperative phase be performed when anticoagulant effects are low (e.g., just prior to administration of the next dose of antithrombotic agent).⁵⁴

Some uncertainty, however, exists regarding the preferred choice of medication, optimal dosing regimen, and time of initiation of thrombosis prophylaxis, particularly in patients with a higher risk for bleeding. Any decision regarding the use of thrombosis prophylaxis must weigh efficacy against harm from the proposed intervention. In addition, early mobilization in the postoperative phase, whenever possible, is recommended. More consensus exists concerning routine administration of anticoagulant therapy in patients with spinal cord injuries.

PREVENTION AND MANAGEMENT OF NEUROSURGICAL POSTOPERATIVE COMPLICATIONS

Supratentorial Procedures

Postoperative Subgaleal Hematoma

Postoperative subgaleal hematoma may occur in up to 11% of procedures. These hematomas generally result from inadvertent damage of

the superficial temporal artery with inadequate hemostasis or hemorrhage from the temporal muscle. If the superficial temporal artery is damaged during the operation, ligation is preferred over coagulation. The occurrence of subgaleal hematomas can be minimized by routine use of postoperative wound drainage for 24 hours. Reoperation for subgaleal hematomas is seldom necessary unless there is a communication with the intracranial compartment with secondary compression of the brain.⁵⁵

Intracranial Hemorrhage

Intracranial postoperative hemorrhage occurs in about 1% of procedures and mainly includes intraparenchymal hematomas (43%-60%), epidural hematomas (28%-33%), and subdural hematomas (5%-7%). After every supratentorial procedure, some blood may accumulate in the epidural space. Appropriate surgical techniques aim to minimize this epidural space by circumferentially suturing the dura to the bone, periosteum, or galea. Nevertheless, inadequate hemostasis of meningeal arteries, blood loss from the temporal muscle, or blood loss from bone or the sites of skull penetration by the pins of a Mayfield clamp may induce a larger postoperative epidural hematoma. In cases of neurologic deterioration considered to be due to a postoperative epidural hematoma, surgical evacuation is indicated. Postoperative subdural hematomas occur less frequently and may develop after a delay, due to later rupture of bridging veins following large intracerebral decompression. On occasion, such subdural hematomas may occur distant from the primary site of operation.

Parenchymal hemorrhages are the most frequent cause of postoperative hematomas after supratentorial procedures and generally occur at the site of operation, particularly following partial tumor resection. An increase in systemic BP at the end of surgery may increase the risk of parenchymal hemorrhage. In rare cases, the hematoma may be located distant from the primary site of operation, and cerebellar hematomas have even been described after supratentorial surgery.^{56,57} The possibility of a postoperative hematoma should be considered in all patients who are not fully alert after anesthesia, as well as in those who exhibit secondary deterioration.

Postoperative Brain Swelling

Modern neuroanesthesiology techniques have diminished the incidence of peri- and postoperative brain swelling. Nevertheless, significant swelling may sometimes occur, causing surgical difficulties and possibly critical problems in the ICU. Predisposing factors are hypercapnia, arterial hypertension, hyponatremia, obstruction of venous drainage, and silent or overt seizures during surgery or in the immediate postoperative phase. Further, significant brain swelling after uneventful surgery has been attributed to intracranial hypotension caused by subgaleal suction.⁵⁸ In any patient with brain swelling during the surgical procedure, the possibility of a deep hematoma should be considered and urgent computed tomography (CT) should be performed. Brain swelling due to vasodilation can be corrected by hyperventilation and barbiturate administration; brain swelling due to cerebral edema should preferentially be treated by osmotic agents.

Tension Pneumocephalus

Some air collection is generally observed on postoperative CT scans.⁵⁹ In rare circumstances, rewarming of air in the intracranial compartment postoperatively or continuous air leakage due to a cerebrospinal fluid (CSF) fistula of the skull base may lead to a tension pneumocephalus, with clinical symptomatology including decreasing level of consciousness, signs of raised ICP, and occasionally seizures. Generally, postoperative air accumulations are self-limiting and do not require specific treatment.

Seizures

An epileptic seizure in the early postoperative phase should be considered a serious complication that may cause significant deterioration because of vasodilation, increased cerebral oxygen consumption, and

increased brain edema. Subclinical seizure activity can occur in 15% to 18% of patients with moderate and severe TBI.⁶⁰ The benefits of prophylactic antiseizure medication should be balanced against risks. In some centers, routine prophylaxis is prescribed in all patients undergoing supratentorial brain surgery. In others, the indications are restricted to patients with a higher risk:

- Cerebrovascular surgery (e.g., arteriovenous malformation, aneurysm)
- Cerebral abscess and subdural empyema
- Convexity and parafalcine meningiomas
- Penetrating brain injury
- Compound depressed skull fracture

Opinions vary regarding the duration of prophylactic antiseizure therapy, with some centers recommending a treatment duration of 1 week and others continuing treatment for at least 3 months. In any case of unexplained neurologic deterioration or delayed awakening from anesthesia, the possibility of seizures should be considered.

Infratentorial Procedures

The care of patients in the early postoperative phase following infratentorial procedures poses specific problems. Postoperative complications in the posterior fossa can lead to rapid deterioration because of the relatively small infratentorial volume reserve and immediate compression of the brainstem, resulting in respiratory insufficiency and acute herniation. Irritation of the brainstem may induce large swings in arterial BP, enhancing the risk of postoperative hemorrhage during hypertensive episodes. Cranial nerves are more susceptible than peripheral nerves to damage caused by surgical manipulation.⁶¹ Lesions of the lower cranial nerves may lead to a diminished gag reflex, increasing the risk of aspiration and pneumonia. After surgery in the cerebellopontine angle, specific attention should be paid to the function of the trigeminal and facial nerves, and prophylactic measures should be taken to prevent damage of the cornea.

After any infratentorial procedure, the risk of acute hydrocephalus due to obstruction at the level of the fourth ventricle is present. In rare instances in which supratentorial CSF drainage is performed, increased pressure in the infratentorial compartment may cause upward (inverse) herniation. These specific aspects warrant routine admission to the ICU of all patients who have undergone posterior fossa surgery to allow careful observation and monitoring. Particular attention should be paid to the presence of the gag reflex before extubation and in the early stages after extubation, and frequent monitoring of the respiratory status and adequacy of respiration is imperative.

After posterior fossa surgery, some patients may develop a syndrome of aseptic meningitis.⁶² This is characterized by meningeal symptoms, headaches, and an inflammatory response of the CSF in the absence of evidence for infection. The origin of this syndrome has not been fully clarified, but symptoms may resolve sooner with intermittent CSF drainage.

An infrequent transitory complication observed after resection of large midline posterior fossa tumors is cerebellar mutism.⁶² The exact cause is poorly understood, but a vascular phenomenon has been hypothesized.⁶³

Cerebrovascular Procedures

The postoperative care for patients undergoing cerebrovascular surgery poses specific challenges in neurointensive care. After surgery for arteriovenous malformations, the risk of seizures is particularly high, and focal deficits may occur secondary to changes in cerebral hemodynamics. Following treatment for a cerebral aneurysm, medical and cerebral complications can occur that are related to the disease or the treatment (surgical clipping or endovascular coiling). Medical complications specifically linked to SAH are neurogenic pulmonary edema, cardiac arrhythmias, and ventricular failure.¹⁹ Electrolyte disturbances, in particular hyponatremia, are also frequently observed.⁶⁴

The main cerebral complications are:

1. Rebleeding
2. Delayed cerebral ischemia (DCI)
3. Hydrocephalus

Rebleeding occurs mainly in the first weeks after aneurysmal rupture, and current approaches to prevent rebleeding involve early surgical clipping or endovascular obliteration (coiling) of the aneurysmal sac. DCI (often the result of vasospasm) is a common cause of death and disability due to SAH, second only to rebleeding. The reported incidence of this complication varies widely, but angiographic vasospasm is seen in over 67% of untreated patients with angiography at the time of maximum spasm, around the end of the first week.⁶⁵

Although DCI may be caused by vasospasm, not all patients with DCI have vasospasm. Conversely, not all patients with vasospasm develop clinical symptoms and signs of DCI. Recent studies show that DCI may not always be attributed to vasospasm but more to the occurrence of microthrombosis.^{66,67} DCI is associated with activation of the coagulation cascade within a few days after SAH, preceding the time window during which vasospasm occurs. Furthermore, both impaired fibrinolytic activity and inflammatory and endothelium-related processes may lead to the formation of microthrombi, further promoting the development of DCI.

Clinically evident delayed ischemic deficits (DID) affect approximately one-third of patients. Various studies have shown a beneficial effect of the administration of oral calcium antagonists in preventing DID.^{68,69} Beneficial effects of intravenous administration of nimodipine remain unproven, however.

Following evidence that patients with SAH had reduced blood volume, plasma volume, and erythrocyte mass, triple H (HHH) therapy (hypervolemia, hypertension, and hemodilution) was proposed for both prophylaxis and treatment of DID after SAH. Various studies have shown a reduction in DID with HHH prophylaxis,⁷⁰ but some debate remains.^{71,72}

The usefulness of HHH treatment is generally accepted, but it has never been unequivocally shown by a randomized controlled trial to be superior to simple moderate fluid loading. The relative importance of the three components of HHH therapy is uncertain.^{73,74} Adequate fluid loading should be considered the most important aspect of early treatment and prophylaxis of DID, but it may be considered reasonable to reserve more vigorous loading and induced hypertension for situations in which there is clinical evidence of delayed ischemia.⁷⁴⁻⁷⁶

Progressive signs of DID may require more aggressive approaches, including angioplasty.⁷⁷ Transluminal balloon angioplasty is generally recommended, but this requires special equipment and a highly skilled and experienced interventional neuroradiology team. Alternatively, so-called chemical angioplasty, in which the angiography catheter is used to install papaverine or nimodipine, may be considered.⁷⁸

Chemical angioplasty often has to be repeated within hours or days, and it carries the risk of complications, including pupillary changes, seizures, or respiratory arrest, with vertebral artery injection. The possibility of cisternal therapy should also be considered, injecting recombinant tissue plasminogen activator or urokinase into the basal cisterns to break down accumulated blood⁷⁹ or nitric oxide donors to improve vascular tone. Various studies have shown clinical benefit of this approach, with the added benefit of reducing the incidence of hydrocephalus.

Acute hydrocephalus after SAH is not uncommon. The reported frequency depends on the criteria used for diagnosis and ranges from 9%⁸⁰ to 67%.⁸¹ Spontaneous improvement of the hydrocephalus has been reported in about half of patients with acute hydrocephalus and impaired consciousness on admission, but it may be difficult to predict spontaneous improvement because treatment is generally instituted. In the absence of a hematoma with mass effect or an obstructive element, serial lumbar punctures may be the initial optimal method of treatment, reserving continuous CSF drainage procedures for patients in whom the hydrocephalus does not resolve over time.

ADMISSION EXAMINATION AND MONITORING IN THE INTENSIVE CARE UNIT

Specific care and monitoring of the postoperative neurosurgical patient require accurate knowledge of the preoperative situation and the intraoperative course, including the surgery, anesthesiology, and any surgical complications or difficulties. Pertinent aspects are summarized in Table 59-3.

On admission to the ICU, a full examination of the patient is required, including, whenever possible, an assessment of the level of consciousness and neurologic functioning. Medical care for the patient should be provided in joint collaboration between an intensivist and neurosurgeon. Intensive care monitoring includes clinical surveillance, technical monitoring, and follow-up CT or magnetic resonance imaging (MRI). The various approaches to monitoring are summarized in Table 59-4. These are discussed in detail in Chapter 47.

Clinical Surveillance

Even in this era with advanced monitoring procedures, routine clinical examinations are essential. The clinical assessment has the purpose of disclosing major, life-threatening complications early after surgery and of assessing and tracking neurologic deficits in the hours to days that follow.

Early Evaluation

A simple check of consciousness, pupils, and the development of focal (mostly motor) deficits remains the most important method for assessing patients in the neuro-ICU. Neurologic assessment should be repeated at regular intervals throughout the ICU course, as a change

in examination findings is the most sensitive method for detecting neurologic deterioration.

The level of consciousness should be assessed by the Glasgow Coma Scale (GCS).^{82,83} In this scale, standardized assessment of three aspects of responsiveness is performed: the eye, motor, and verbal reaction (Table 59-5). When administration of stimuli is necessary to assess the level of responsiveness, standardized administration is required. Pressure on the nail bed is recommended as a peripheral stimulus, and supraorbital pressure or trapezius pinch is recommended as a central stimulus when testing for a localizing response on the motor scale (Fig. 59-1). Accurate determination of the full GCS is not always possible because of sedation and paralysis, but at least the best motor score should be recorded, when possible. Daily interruption of sedation allowing intermittent wake-up in ventilated patients not only facilitates monitoring of the neurologic status, but it has also been shown to result in better outcomes.⁸⁴

Some authors advocate imputing the eye and verbal scores from the motor score in sedated and/or ventilated patients.⁸⁵ We prefer an approach in which only the motor score is assessed at times when the level of sedation permits, as this is an important parameter of neurologic function and the main predictor of outcome in unconscious patients. Reasons for not being able to assess one of the components of the GCS should be recorded. When used for describing the level of

Notes: the best score for each response should be documented and communicated in the format described above. Assessment of the best motor score is based on the best response of the arms. For use in individual patients, separate descriptions of the three components of the Glasgow Coma Scale (GCS) are strongly recommended. For purposes of classification, the total GCS can be calculated by adding the best score obtained in each category. The GCS should be annotated to indicate confounding factors: T = intubated patient, S = sedation, and P = neuromuscular blockade.

consciousness in an individual patient, the three components of the GCS should be described separately. For purposes of classification and research, the GCS sum score can be calculated.⁸³

The development of pupillary abnormalities is a sensitive indicator of pressure on the midbrain (tentorial herniation). The pupillary reaction to light is mediated through parasympathetic fibers of the third cranial nerve (oculomotor nerve). Afferent light perception, conducted through the second cranial nerve (optic nerve), connects at the level of the internal eye muscle nuclei to the oculomotor nerve supplying parasympathetic fibers to the sphincter pupillae muscle via the ciliary ganglia.

Pressure on the oculomotor nerve leads to loss of function of the parasympathetic fibers, causing a diminished pupillary response or absent pupillary reactivity, generally located initially on the side of the lesion (Fig. 59-2). With a progressive increase in pressure, both pupils become dilated and unresponsive to light. In patients with a lesion of the optic nerve, the consensual light reflex—contraction of the pupil when a light is shone into the opposite eye—remains intact.

Pupillary examination (of diameter and light reactivity) may be difficult in the ICU, where lightening is usually intense. It is especially difficult in patients under the effects of opioids, as these drugs cause miosis. In these circumstances, a computerized system known as *pupillometry* is available for precise assessment of pupil diameter and constriction to light.⁸⁶⁻⁸⁹

Further Evaluation

When major complications have been ruled out, it remains necessary to evaluate the persistence of previous deficits, their improvement after surgery, or the appearance of new signs attributable to surgery. It is expected, for example, that following surgical removal of a vestibular schwannoma, some degree of damage to cranial nerve VII can occur. After surgical intervention on structures located in, or close to, the brainstem, deficits of the lower cranial nerves can occur as well. A careful, complete neurologic examination is required at this stage, since the simple assessment proposed in the previous section is not meant to fully evaluate cranial nerve function. This evaluation is important since the presence of cranial nerve deficits may require action: for

example, protection of the ocular bulb to prevent keratitis or avoidance of oral feeding if swallowing is impaired.

SYSTEMIC MONITORING: CARDIOPULMONARY STATUS, RESPIRATORY STATUS, AND TEMPERATURE

The goal of cardiopulmonary and respiratory monitoring is to ensure adequate control of systemic hemodynamic and respiratory function, which is essential for optimization of cerebral oxygenation. Invasive arterial BP monitoring is recommended, with the reference point set at the same level as the ICP measurement to allow accurate calculation of the cerebral perfusion pressure (CPP).

The combination of a careful prescription of maintenance fluids, additional replacement solutions tailored to the patient's needs, and a rational but not aggressive goal-directed approach to resuscitation fluids seems to be the best approach to avoiding fluid-related morbidity in the perioperative period, including after neurosurgery.⁹⁰

Hypovolemic shock is most common in the setting of multisystem injury or intraoperative blood loss with inadequate replacement. Tachycardia and signs of peripheral vasoconstriction, such as skin pallor and poor capillary refill, may precede a drop in BP. To achieve rapid fluid resuscitation, therapeutic options include isotonic crystalloid fluids, volume expanders, small volume resuscitation (hypertonic saline), and blood transfusions. Isotonic balanced crystalloids seem to be the best pragmatic choice for resuscitation purposes.⁹⁰ Colloids, and particularly albumin, should be used with caution or even avoided in patients with several central neurologic disorders. Post hoc analysis of critically ill patients with TBI included in the Saline versus Albumin Fluid Evaluation study revealed that fluid resuscitation with albumin was associated with higher mortality rates than resuscitation with saline.⁹¹

Central venous pressure monitoring or cardiac output monitoring can guide the use of intravenous fluids and vasopressor therapy, aiming to optimize organ perfusion. Several hemodynamic monitors and parameters may be useful for guiding volume therapy, including cardiac output, stroke volume variation monitoring, and global end-diastolic volume index.⁹² Early goal-directed hemodynamic therapy after SAH has been shown to improve clinical outcomes in patients with a poor clinical grade or coexisting cardiopulmonary complications.⁹²

After initial volume resuscitation, we suggest a hematocrit of approximately 30% to 33% as optimal in the acute postoperative period in patients in the neuro-ICU. Although debate still exists, available evidence suggests that restrictive blood transfusion strategies may be less appropriate in neurointensive care.⁹³⁻⁹⁷ However, a 2014 randomized clinical trial in TBI, which compared two hemoglobin transfusion thresholds (7 versus 10 g/dL), found no difference between groups in neurologic outcomes but a higher incidence of adverse events in the group managed at the higher hemoglobin level.⁹⁸ Most likely, treatment should be individualized, aiming at optimal oxygen delivery to the brain for those patients who need it most. After intracranial or spinal cord procedures, we would advocate a more liberal use of blood transfusions than generally recommended in intensive care medicine, aiming for a hemoglobin of at least 5.5 to 6.0 mmol/L (approximately 9.0-9.5 g/dL) in order to promote adequate oxygenation of the CNS.

FIGURE 59-1 ■ Supraorbital and nail bed pressure for assessment according to the Glasgow Coma Scale.

FIGURE 59-2 ■ Pupillary reactivity and size.

This corresponds to the recommendations proposed by Goodnough et al.⁹⁹ in cases of ischemia.

Cardiogenic shock due to primary loss of cardiac function is uncommon in neurosurgical patients, but it may occur, especially in elderly patients with secondary cardiac ischemia or arrhythmias or patients with takotsubo syndrome. These patients may require sequential echocardiographic follow-up and/or cardiac output monitoring to optimize volume status and cardiac output.

Large pulmonary emboli, sepsis, or spinal paraplegia should be considered in patients with systemic hypotension. In patients with spinal distributive shock, typically the hypotension is associated with bradycardia, with a heart rate in the range of 35 to 50 bpm. These patients should not be managed with excessive volume resuscitation but rather with vasopressors to restore alpha-adrenergic peripheral vasomotor tone. The combination of hypertension and bradycardia (Cushing response) should alert the physician to the potential of an expanding intracranial lesion and risk of brainstem herniation. In this situation, the use of antihypertensive agents is contraindicated, and therapy should be aimed at the raised ICP.

Temperature monitoring is important in the neuro-ICU, since hyperthermia can depress neurologic function to the point of obtundation or coma. Conversely, fever, by increasing metabolic requirements, may exacerbate secondary injury. Mean energy expenditure may be increased up to 200% in patients following brain injury,¹⁰⁰ and it would, therefore, appear appropriate to not risk increasing metabolic requirements even further. Thus, we recommend that core temperature should be kept below 38.0°C, using medications (e.g., acetaminophen, diclofenac) and external or intravascular cooling.

Hypothermia may be due to adrenal or pituitary insufficiency, hypothalamic disorders, hypoglycemia, or intraoperative exposure. Deliberate hypothermia is sometimes used in complicated cerebrovascular procedures and as third-tier therapy in patients with TBI to reduce ICP. For TBI, hypothermia has been shown to effectively reduce ICP, but conflicting results have been reported regarding its clinical benefits.^{101,102} The recent Eurotherm trial, in which patients with raised ICP were randomized to hypothermia or other second-tier therapies, was halted prematurely after enrollment of 387 patients because of safety concerns. In the final analysis, outcomes were statistically significantly poorer in patients treated with hypothermia.¹⁰² One difference between Eurotherm and other randomized controlled trials examining hypothermia for TBI is that Eurotherm was conducted in a large number of countries and centers (47 centers across the world). Even if hypothermia may produce some benefit in high-level research centers, the results of Eurotherm have unequivocally demonstrated that it is harmful in broader settings.¹⁰²

Various approaches to cooling have been adopted, but the most frequently used employ surface cooling or gastric lavage with cold fluids. Marion¹⁰³ reported favorable results with the use of devices for intravascular cooling, and this technique can be expected to become standard for induction of hypothermia in the near future.

Hypothermia has been associated with several complications, including cardiovascular instability (mainly arrhythmias), coagulopathy, electrolyte shifts, fluid overload, and increased risk of infection and shivering.^{104,105} The management of a patient treated with hypothermia over longer periods of time for control of raised ICP can be much more complex than the use of short-term hypothermia after cardiac arrest. Ideally, normothermia could represent the best trade-off between the dangers of hyperthermia and the complexities and side effects of hypothermia. In practice, a trial in neurointensive care comparing conventional treatments to hyperthermia with prophylactic normothermia, induced and maintained with intravascular cooling systems, has failed to show benefit.¹⁰⁶ (See annotated references for further details.)

Biochemical Parameters: Electrolytes, Osmolarity, and Blood Glucose

The major focuses in neurointensive care are to prevent and limit brain damage and to provide the best conditions for natural brain recovery

from surgery or injury by ensuring optimal oxygenation, perfusion, ionic homeostasis, glycemic control, and temperature management. Keeping biochemical parameters within their physiologic range is desirable but challenging. Repeated determinations are necessary for early detection of derangements and to prevent overcorrection. Patients with comorbidities (e.g., diabetes, cardiac failure) and concomitant medications are especially at risk.

Electrolytes and Osmolarity

A direct link exists between plasma osmolarity and water flux into and out of brain cells.^{107,108} If the blood-brain barrier is intact, any decrease in plasma osmolarity will cause an increase of intracellular water within the brain, potentially leading to an increased ICP, altered transmembrane potentials, and other changes.¹⁰⁹ It is, hence, important to prevent the development of hyponatremia, as this may exacerbate the development of brain edema in the postoperative setting. Particularly in pediatric patients undergoing external CSF drainage, replacement of drained CSF by physiologic saline is recommended.

Various factors may contribute to the high risk of electrolyte disorders in neurointensive care:

- Use of osmotically active drugs (e.g., mannitol, hypertonic saline [HTS], or other diuretics) for the treatment of raised ICP. These may induce electrolyte derangements or increase serum osmolarity to levels that compromise kidney function. Careful and frequent monitoring is, therefore, required. The general recommendation is that serum osmolarity should be kept below 320 mOsm/L. When using hypertonic saline, serum sodium should be kept below 160 mmol/L.
- Common use of steroids in brain surgery to prevent cerebral edema. These may increase blood glucose to levels that exceed the maximum renal capability for glucose transport. If glycosuria follows, it causes osmotic diuresis.
- Reduced release of antidiuretic hormone (ADH) secondary to surgery or injury impacting neurohypophyseal function, which leads to sudden episodes of diabetes insipidus.¹¹⁰ In addition to administering exogenous ADH, large urinary volumes have to be replaced with appropriate solutions to preserve euvolemia and normal serum osmolarity.
- Cerebral salt wasting. This disorder is still poorly understood¹¹¹ and is often difficult to differentiate from inappropriate ADH syndrome. Fluid restriction for correction should generally be avoided; it is often better to administer hypertonic saline.

Glucose

Glucose is an essential substrate for brain metabolism, and every effort should be made to ensure adequate glucose delivery to the nervous tissue. In general intensive care, tight glycemic control has been advocated based on the knowledge that outcomes are poorer in the presence of hyperglycemia and following the results of the study by van den Bergh et al.¹¹² showing reduced mortality of surgical intensive care patients by keeping glycemia within narrow limits (80–110 mg/dL). These findings have, however, been challenged in subsequent studies.¹¹³

Although various studies in neurointensive care patients have demonstrated an association between elevated glucose levels and poorer outcome,^{114–117} the question remains whether this association is causal or not. In neurointensive care, the particular concern is that the injured brain cannot tolerate hypoglycemia, which might occur as an adverse event from overly enthusiastic glycemic control. There is a strict relationship between increased use of insulin (for tight glycemic control) and the occurrence of hypoglycemia.^{118,119} Moreover, lowering blood glucose to “normal” levels may result in unacceptably low levels of glucose in the brain, depriving the most complex organ in the human body of its most essential metabolic substrate. Evidence for this concern has been shown using microdialysis.^{120–122}

These observations illustrate the complex interactions between systemic and cerebral parameters and highlight that correction of

biochemical parameters in the blood may not always be good for the brain, particularly when recovering from surgery or injury. The currently available evidence does not support the use of tight glucose control in the neuro-ICU.

BRAIN MONITORING AND SPECIFIC THERAPEUTIC APPROACHES

In comparison to the setting of cardiac intensive care, the possibilities for brain monitoring are limited.¹²³ In cardiac care, routinely measured parameters include a multitude of pressure indices and a number of different serum markers (e.g., creatine kinase fractions, troponin) to determine whether the heart is at risk for further injury. Physiologically, the heart is monitored by electrocardiography and intermittent echocardiography. In contrast, routine brain monitoring is restricted in most centers to ICP and CPP monitoring. The field is, however, rapidly evolving. Monitoring of cerebral oxygenation is now being increasingly implemented into practice,¹²⁴⁻¹²⁶ and continuous electroencephalography (EEG) is performed in some centers.¹²⁷⁻¹²⁹ MRI spectroscopy offers opportunities to noninvasively assess brain metabolism.^{130,131} Advances in the field of biomarkers offer hope that detection and tracking of pathophysiologic processes in the brain may be within reach.¹³²⁻¹³⁵ Different markers are relevant to different stages after injury. In the acute and subacute phases, cellular degradation products and markers of inflammatory responses have potential usefulness, while in the chronic phase, markers of neurodegeneration are being explored for in vivo detection of degenerative disorders linked to brain injury, such as chronic traumatic encephalopathy and Alzheimer's disease. In patients with severe TBI, increased levels of S-100B and neuron-specific enolase have been shown to be correlated with increased ICP, decreased CPP, and more structural damage visualized on CT scanning.¹³⁶ A clear association between increased levels of glial fibrillar acidic protein and ubiquitin C-terminal hydroxylase L1 (glial and neuronal markers) and poorer outcome has been confirmed.¹³⁷

Current approaches to brain-specific monitoring include measurements of ICP, cerebral oxygenation, and cerebral blood flow (CBF), as well as electrical monitoring and metabolic monitoring. These specific modalities are discussed in detail in Chapter 47. Here, we focus on essential aspects of the interpretation of the monitoring results and their therapeutic implications.

Intracranial Pressure and Cerebral Perfusion Pressure

ICP monitoring is most commonly performed in trauma patients. It is indicated in patients with a severe brain injury (GCS < 8) with abnormalities on the initial CT scan and in patients with a normal admission CT scan if two or more of the following features are present: age more than 40 years, unilateral or bilateral motor posturing, or systolic BP below 90 mm Hg.

Routine ICP monitoring is generally not indicated in patients with mild or moderate TBI, but it may be considered when other severe extracranial injuries are present, necessitating anesthesia for surgery, or when the initial CT shows traumatic lesions with space-occupying effects.¹³⁸ ICP monitoring is further indicated in poor-grade patients with SAH.¹³⁹⁻¹⁴¹ Further, it may be considered in patients with other intracranial disorders who are sedated and ventilated and who are considered to be at risk of developing raised ICP (e.g., postoperative swelling, stroke, Reye's syndrome). The value of ICP monitoring has been questioned by some since publication of the BEST-TRIP trial that showed no difference in outcome between patients with TBI treated according to ICP monitoring versus those in whom "ICP-targeted" therapy was based on clinical observation and CT scanning.¹⁴² ICP monitoring, however, contributes to a better characterization of the pathophysiology and, thus, facilitates precise treatment approaches. Recommendations regarding the indications for and techniques of ICP monitoring in various disease states were recently summarized.¹⁴³

ICP monitoring carries a 0.5% risk of hemorrhage and a 2% risk of infection.¹⁴⁴ Intracranial hemorrhages are a rare complication of ICP monitoring and are usually caused by multiple punctures in the presence of a coagulopathy. The risk of infection is higher for ventricular monitoring, and the rate of infection is proportional to the duration of monitoring.¹⁴⁵ Intraventricular catheters are preferable because they are accurate, can be recalibrated, and allow drainage of CSF. Intracranial probes are user-friendly and accurate. Less accurate data are provided by subdural catheters,¹⁴⁶ and epidural probes are unreliable.^{147,148} The accuracy of ICP monitoring can be enhanced by use of computer-supported systems.¹⁴⁹ Attempts to monitor ICP noninvasively have been unsatisfactory.^{150,151}

Relatively few data exist regarding routine ICP monitoring in the postoperative period. In a series of 30 patients after severe TBI and elective craniectomy, 156 instances of ICP increases and/or CPP decreases were recorded.¹⁵² These were accompanied by clinical deterioration in only 15 cases. Telemetric ICP control has been proposed for use after posterior fossa surgery.¹⁵³ In a series of 514 patients after supra- and infratentorial surgery, Constantini et al.¹⁵⁴ described raised ICP in 13% and 18% of cases, respectively. Neurologic deterioration occurred in about half of the patients with an ICP rise, and deterioration was always preceded by the ICP increase. In a series of 780 patients submitted to routine ICP monitoring after intracranial surgery, 47% required ICP-directed therapy.¹⁵⁵ In a report involving 850 cases, Bullock et al.¹⁵⁶ concluded that ICP monitoring allows earlier identification of recurrent hematomas. These data would support more routine use of ICP monitoring after intracranial surgery, particularly in more complex cases. In some institutions, ICP is routinely measured as part of postoperative surveillance after major neurosurgical procedures, especially when there is the risk of postoperative bleeding. Figure 59-3 illustrates a case in which a substantial ICP rise was detected in the first postoperative hours. It was caused by an enlarging hemorrhage that required reintervention.

Normal values for ICP are up to 15 mm Hg in adults. Consensus exists that ICP should preferably be maintained below 20 mm Hg. The absolute value of ICP measured should, however, never be considered in isolation. More important is the trend over time and the relationship to the arterial BP. CPP is calculated as:

$$CPP = MABP - ICP$$

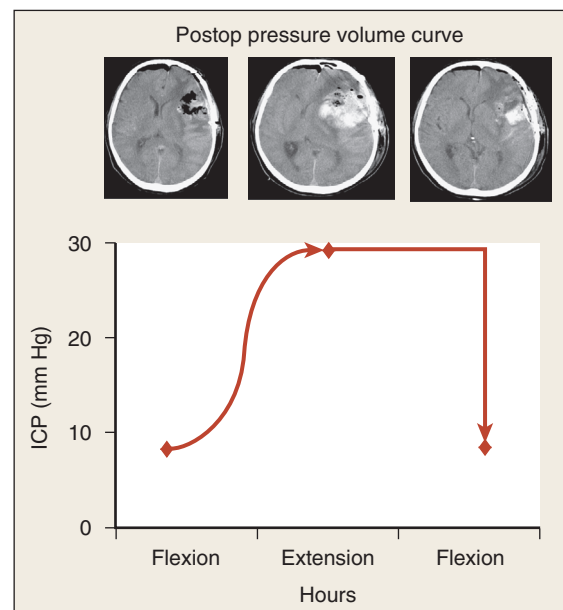

FIGURE 59-3 ■ Raised intracranial pressure (ICP) as the first indication of a developing postoperative hematoma.

BOX 59-1**Remediable Extracranial Causes of Intracranial Hypertension**

Calibration errors
 Airway obstruction (kinked endotracheal tube, tongue, sputum retention, pneumothorax)
 Hypoxia (low inspired oxygen concentration, lung disease or collapse)
 Hypercapnia (hypoventilation)
 Hypertension (pain, sedation, coughing or straining)
 Hypotension (hypovolemia, sedation, cardiac)
 Posture (Trendelenburg position, neck rotation)
 Hyperpyrexia
 Seizures
 Hypoosmolality (low sodium, protein)

Physiologic and nonphysiologic ICP waveforms may occur. Technical artifacts and systemic causes should be excluded before specific diagnostic procedures are instituted or ICP-directed therapy initiated or intensified (Box 59-1).

In some patients, the normal pressure autoregulatory mechanisms are disturbed, and the risk exists that increasing the CPP may worsen cerebral edema. Careful observation of the change in ICP with respect to arterial BP changes is required to determine whether autoregulation is disturbed or intact. For continuous evaluation of the autoregulatory status, it has been proposed that the pressure reactivity index (PRx) be calculated, as a moving correlation coefficient between MABP and ICP.¹⁵⁷⁻¹⁵⁹ PRx is easy to monitor because it is available as long as an ICP probe and arterial line are in place. Continuous monitoring with PRx can be used to provide individual thresholds in CPP-oriented management of trauma patients in the ICU, by revealing the optimal CPP for pressure reactivity.¹⁶⁰ Use of autoregulation monitoring offers a promising perspective for better characterization of pathomechanisms, but confirmation of the anticipated benefits of optimal CPP-directed management is required.

Treatment of Cerebral Herniation and Elevated Intracranial Pressure

The development of cerebral herniation (tentorial herniation or cerebellar tonsillar herniation) constitutes a neurosurgical emergency. Rapid intervention is required prior to further investigations to determine the cause. According to the concept of the pressure-volume curve (Fig. 59-4), a small reduction in intracranial volume will significantly decrease a raised ICP and may reverse herniation. The emergency measures to be taken include:

- Ventricular CSF drainage (if access is available)*
 - Bolus administration of high-dose hyperosmolar agents (mannitol 1-1.5 g/kg body weight; HTS: 7.5% saline 1-2 mL/kg body weight, infused over 5 min)
 - Rapid-sequence intubation and moderate hyperventilation
- Following these emergency procedures, an emergency head CT scan should be performed to detect the cause of the raised ICP and permit targeted treatment, such as evacuation of a postoperative clot or further treatment of acute obstructive hydrocephalus.
- The main intracranial causes of raised ICP are:
- Mass lesions (e.g., hematoma)
 - Edema (vasogenic, cytotoxic, osmotic, or hydrostatic)
 - Increased cerebral blood volume (e.g., vasodilation)
 - Disturbance of CSF flow (e.g., hydrocephalus, benign intracranial hypertension)

In the absence of acute cerebral herniation, elevated ICP is addressed first by ruling out treatable intracranial mass lesions and remediable extracranial causes or to monitor malfunction (see Box 59-1).

*Lumbar CSF drainage should never be attempted in this situation, as it may exacerbate the herniation.

FIGURE 59-4 ■ Intracranial pressure (ICP)-volume curve.

When appropriate, surgical intervention is indicated. Conservative therapy of elevated ICP includes these first- and second-tier approaches:

- Sedation, analgesia, and mild to moderate hyperventilation (arterial carbon dioxide partial pressure [PaCO_2]: 4-4.5 kPa [30-35 mm Hg])
- Osmotic therapy: preferably mannitol given as a bolus infusion (dose: 0.25-0.5 g/kg body weight or as indicated by monitoring). Alternatively, HTS may be considered. Effective bolus doses range between 1 and 2 mL/kg of 7.5% saline. Effective continuous infusion doses range between 75 and 150 mL/hour of 3% saline. Although comparing the effectiveness of mannitol versus HTS is often confounded by the wide variability in concentrations and doses used for HTS, a recent study reported that HTS given as bolus therapy was more effective than mannitol in lowering the cumulative and daily burden of ICP in patients with TBI.¹⁶¹ Table 59-6 presents an overview of the osmolality and electrolyte concentrations of different commercially available hypertonic solutions used for treating raised ICP. Serum osmolality should be maintained below 320 mOsm/L and serum sodium below 160 mmol/L if possible. Particular vigilance is warranted when mannitol and HTS are given concomitantly. If osmotherapy has insufficient effect, furosemide can be given additionally.
- CSF drainage
- Volume expansion and inotropes or vasopressors when arterial BP is insufficient to maintain CPP and CBF in a normovolemic patient
- If these methods fail, third-tier therapies for raised ICP include:
 1. Mild or moderate hypothermia
 2. Decompressive surgery
 3. Administration of barbiturates
 4. More intensive hyperventilation (which should be accompanied by monitoring cerebral oxygenation to detect cerebral ischemia)

Cerebral Blood Flow

The past decade had witnessed great advances in approaches to monitor CBF and CBF-related variables, particularly from the field of neuroimaging. Both CT and MRI techniques have been developed for perfusion imaging and angiography. Thus, possibilities for determination of areas of the brain at risk for ischemia are now routinely available to the clinician. These approaches have replaced measurements of CBF with stable xenon CT scanning. Positron emission tomographic studies for CBF and metabolic studies of the brain have largely remained in the domain

TABLE 59-6

Composition of Different Commercially Available Hypertonic Solutions Used for Treatment of Raised Intracranial Pressure Compared to Isotonic Solutions (*)

| DRUG | OSMOLARITY (mOsm/L) | SODIUM (mmol/L) | CHLORIDE (mmol/L) | COLLOID |
|-------------------------|---------------------|-----------------|-------------------|---------|
| Ringer's lactate (*) | 277 | 130 | 112 | — |

HES, hetastarch; NaCl, sodium chloride.

of research. Thermal diffusion flowmetry has been introduced as a bedside technique to continuously monitor CBF, but experience with this method is limited.^{146,162,163} A major drawback of this sensor is that it is not MRI compatible. Transcranial Doppler (TCD) provides a noninvasive assessment of blood flow velocity through the basal cerebral arteries. TCD is widely used to detect and track cerebral vasospasm,¹⁶⁴ but various studies have shown a disappointing correlation when measured flow velocities are compared with measurements of CBF.^{165,166} In patients with stroke, detection of emboli is possible with most current TCD devices.¹⁶⁷

Vasopressors may be needed in the postoperative care of patients in the neuro-ICU. They are often required to treat SAH and severe TBI (see Chapters 50 and 53). It is important, however, to realize that the pathophysiologic mechanisms in the two diseases differ, and that commonly employed approaches for treatment of DID following aneurysmal SAH cannot be directly translated to TBI.

In analogy to the laws of electricity, in which current (I) is dependent on voltage (V) and resistance (R) according to the formula $I = V/R$, CBF is dependent on the driving pressure (CPP) and cerebrovascular resistance (CVR):

$$CBF = CPP/CVR$$

With reference to the Hagen-Poiseuille equation, CVR is determined by the radius and length of the blood vessel and the viscosity of the blood according to the formula:

$$\frac{8 \eta l}{k \pi r^4}$$

where k = a constant, r = radius of the blood vessel, l = length of the blood vessel (which is essentially constant), and η = dynamic blood viscosity. The most powerful factor in this equation is the vessel radius.

The concept behind HHH and CPP therapy is that if CVR is increased, a high driving pressure is required to overcome the increased resistance. After SAH, multiple mechanisms, including cortical spreading ischemia, may contribute to delayed ischemia. Even if vasospasm is not the only cause of reduced brain perfusion, however, it may cause substantial CBF reduction. To maintain cerebral perfusion, a considerable elevation of CPP is required. By contrast, in patients with TBI, the major basal cerebral arteries are not clearly constricted in the acute phase, and it is still uncertain whether the observed reductions of CBF in the acute phase after injury are caused by vasoconstriction within the microcirculation or are secondary to decreased metabolic requirements, possibly due to mitochondrial dysfunction. Furthermore, after TBI, the normal pressure autoregulatory mechanisms may be disturbed, and the risk exists that increased CPP may worsen cerebral edema.

TABLE 59-7

Vasopressors Commonly Used in the Neurocritical Care Unit

| AGENT | ADRENERGIC EFFECT | DOSES ($\mu\text{g/kg/min}$) IN ADULTS |
|----------------|--|--|
| Norepinephrine | Mixed α and β ($\alpha \gg \beta$) | 0.02-1.5 |
| Phenylephrine | Pure α | 0.1-9.0 |
| Adrenaline | Mixed α and β ($\alpha > \beta$) | 0.1-1.0 |

The use of dopamine, a precursor of norepinephrine, has been mainly abandoned because of interference with hormone secretion.

The vasopressors most frequently used in the care of the postoperative neurosurgical patient are listed in Table 59-7. Dose ranges are provided, but it is generally recommended that the required dose be titrated to achieve the desired BP or CPP.

Cerebral Oxygenation and Metabolism

Three approaches to the monitoring of cerebral oxygenation are available to the clinician. These include jugular bulb oximetry (measuring jugular venous oxygen saturation [SjVO_2]), noninvasive cerebral oximetry (i.e., near-infrared spectroscopy [NIRS] determination of regional venous oxygen saturation [Somanetics] or tissue index of oxygenation [Hamamatsu]), and cerebral parenchymal oxygen monitors (measuring brain tissue oxygen tension [PbO_2] [LICOX; Raumedic]).

Global cerebral oxygenation may be assessed using jugular venous oximetry, which is discussed in Chapter 47. When hemoglobin concentration and arterial hemoglobin oxygen saturation remain constant, the arteriojugular difference in oxygen content may be estimated by simply recording the SjVO_2 . A decrease in SjVO_2 indicates that the brain is extracting more oxygen, suggesting that the oxygen supply is not adequate for metabolic demands. Values below 55% indicate increased oxygen extraction relative to perfusion and suggest the presence of ischemia.^{165,168,169}

Interpretation of the results of jugular venous oximetry requires that both systemic information (hemoglobin concentration and arterial oxygen saturation), as well as intracranial data (CPP), be combined. The technique has several limitations. First, continuous monitoring of SjVO_2 with fiberoptic devices is prone to artifact, and second, under conditions of anemia or arteriovenous shunting, hypoxia may be present at the tissue level despite normal values of SjVO_2 .¹⁷⁰ Moreover,

SjVO₂ is a measure of global cerebral oxygenation and does not reflect disturbances due to focal lesions, thus potentially failing to detect ischemia in relevant portions of brain tissue.¹⁷¹

NIRS is a noninvasive technique that permits estimation of oxyhemoglobin, deoxyhemoglobin, and oxidized cytochrome oxidase over the combined arterial, capillary, and venous compartments.¹⁷² Various assumptions are made in the algorithm for calculating cerebral oxygen saturation with NIRS, which may not always be valid, and uncertainty exists whether NIRS, as claimed, mainly measures the intracranial compartment or whether the recorded values are “contaminated” by the extracranial compartment.¹⁷³ The main clinical applications are in neonatology and coronary or carotid artery surgery.^{174,175} Recent intracranial surgery and subcutaneous swelling or wounds to the scalp, which are common in patients with TBI, preclude use of this technique. We, therefore, do not consider NIRS suitable for routine use in monitoring oxygenation in patients undergoing neurosurgical operations, but a noninvasive technique to assess cerebral oxygenation is attractive, and further clinical research is encouraged.

Monitoring Pbo₂ is possible by inserting an oxygen-sensitive electrode into the cerebral cortex or white matter. By definition, this represents a regional technique, and there is still considerable debate whether it should be employed in relatively undamaged parts of the brain (and thus represent more global oxygenation and metabolism) or whether it should be preferably used in the penumbra zone of lesions, with the aim being to limit secondary damage in potentially viable regions. Pbo₂ indicates the balance between oxygen delivered to the tissue and oxygen consumption in a specific area, and Pbo₂ can indicate regional hypoxia if it falls below 15 to 20 mm Hg.^{176,177} The diameter of microvascular vessels and diffusion barriers might also influence recorded values.^{178,179} In TBI, low values of Pbo₂ occur in over 50% of patients during the first 24 hours, and the depth and duration are related to outcome. Increased hyperventilation has been shown to further reduce Pbo₂.^{171,178} Experimental and clinical evidence suggests that CPP therapy may be targeted toward appropriate levels, based on the results of Pbo₂ monitoring.¹⁸⁰ Nonrandomized studies have indicated benefit of a Pbo₂-targeted protocol.¹⁸¹⁻¹⁸³

Microdialysis

The technique of microdialysis involves catheter insertion into the cerebral parenchyma to enable continuous sampling of extracellular cerebral fluid. It allows for the measurement of metabolites (glucose, lactate, and pyruvate) and amino acids (glutamate), as well as indicators of cerebral damage (glycerol or proteins, such as tau or beta-amyloid), in the extracellular fluid of the brain.¹⁸⁴⁻¹⁸⁷ Dialysate fluid obtained after infusing saline through a semipermeable membrane reflects the composition of the extracellular fluid around the probe. Microdialysis is employed in various specialized neuro-ICUs, mainly for research purposes. Technical and logistic considerations, as well as delays in obtaining real-time values, have hindered routine application of the results toward individualized targeted treatment. The availability of microdialysis catheters with a high cut-off membrane now permits detection of larger molecules and may offer opportunities for tracking the inflammatory response.¹⁸⁸⁻¹⁹³

Electrical Monitoring

Continuous EEG (cEEG) monitoring has the potential for detecting nonconvulsive status epilepticus in ICU patients. As a primary monitor of brain function, cEEG can be used to titrate continuous infusions of sedatives, and the technique can further alert physicians to the development of focal or global ischemia.^{194,195} The sensitivity for detecting ischemia and hypoxia is high, but the specificity is low because of the effects of sedatives. cEEG may permit detection and treatment of these adverse events at an early stage, with a potentially positive effect on outcome.¹⁹⁶ Electroencephalographic bispectral analysis may also be useful in assessing the level of sedation in neurocritical care patients.¹⁹⁷

In the research setting, interest exists in monitoring cortical spreading depression. Traumatically damaged neurons decrease their firing

BOX 59-2 Main Approaches in Neuroprotection

- Strategies aimed at improving metabolism and microenvironment
- Examples: hypothermia, mannitol
- Agents acting on specific mechanisms
- Examples: anti-inflammatory agents, apoptosis inhibitors, calcium channel antagonists, neurotransmitter-targeted agents, free radical scavengers, inhibitors of lipid peroxidation
- Pluripotent agents affecting various mechanisms (so-called dirty drugs)
- Combination therapies (including sequential administration)
- Strategies promoting cell survival and regeneration (cellular replacement, gene therapy, and neurotrophic factors)

rates substantially in the early post injury period. Waves of depolarization result in ionic flux and loss of resting membrane potential, which worsens neurochemical dysregulation and places extra metabolic demands on damaged tissues.¹⁹⁷⁻²⁰¹ Measurement of evoked potentials,²⁰² assessing the integrity of sensory and motor pathways, may provide diagnostic and prognostic information, but because of the complexity of this technique, it is not recommended for general use.

NEUROPROTECTION

The original concept of neuroprotection depended upon the initiation of treatment before the onset of an event leading to brain damage, and the methods employed aimed to minimize the intensity of an insult or its immediate effects upon the brain.

Over the past decades, the concept of neuroprotection has been extended to include treatment started after the onset of an insult, reflecting our increased understanding of progressive pathophysiologic mechanisms causing and/or enhancing secondary brain damage. In neuroprotection, four main approaches can be discerned (Box 59-2).

Strategies Aimed at Improving Metabolism and Microenvironment

Methods for improving metabolism and the microenvironment include hypothermia to minimize the effects of energy failure and hyperosmolar therapy to reduce ICP and improve CBF. Hypothermia decreases CBF by about 5.2% per degree reduction in body temperature. The cerebral metabolic rate for oxygen (CMRO₂) and arterial-venous oxygen difference (AVDO₂) fall after the institution of moderate hypothermia. This reflects a reduction in energy requirements and, hence, less energy loss in the injured brain. Many other effects of hypothermia, such as stabilization of cell membranes²⁰³ and reduction of neurotransmitter turnover, may also contribute to the benefits seen in models of ischemia.²⁰⁴ Consequently, hypothermia is currently seen more as a neuroprotective approach than as a metabolic depressant. The use of hypothermia is, however, not without risks and requires high-level neurointensive care.

Hyperosmolar therapy is widely used in neurosurgery to treat raised ICP, decrease brain bulk during intracranial operations, and treat cerebral ischemia. Hypertonic fluids are considered to exert beneficial effects by two mechanisms:

1. Immediate plasma-expanding effect, reducing the hematocrit and blood viscosity and consequently increasing CBF and cerebral oxygen delivery
2. Osmotic effect, which is delayed for 15 to 30 min, while gradients are established between the plasma and cells. Hypertonic solutions may be given in acute emergency situations, such as cerebral herniation, or as part of a conservative approach to treat raised ICP.

Agents Acting on Specific Mechanisms

An increased understanding of the existence of progressive pathophysiologic mechanisms causing or enhancing secondary brain damage has led to the development of a large range of specifically targeted, neuroprotective agents aimed at ameliorating these mechanisms.²⁰⁵

Although marked beneficial effects have often been shown in experimental studies, these promising results have unfortunately not translated into clinical efficacy. In addition to the heterogeneity of patient populations, the lack of clinical parameters to identify mechanistic targets has contributed to these failures. The emerging field of biomarkers and advanced neuroimaging offer hope for the future.

Pluripotent Agents and Combination Therapies

The realization that various pathophysiologic mechanisms are frequently concurrently or sequentially active has increased interest in the use of agents with multiple mechanisms; for such agents, the term *dirty drugs* has been coined.²⁰⁶ Corticosteroids, barbiturates, and magnesium are examples of pluripotent neuroprotective agents. Despite their efficacy in treating vasogenic edema encountered in brain tumors, corticosteroids are not efficacious in improving cytotoxic edema seen after TBI or SAH. Various studies support a neuroprotective effect of magnesium in patients with SAH.^{207,208} A 2010 randomized, controlled trial, however, could not confirm benefit.²⁰⁹ In TBI, greater mortality and poorer outcomes were found in a randomized clinical trial investigating the efficacy of magnesium.²¹⁰ Erythropoietin, cyclosporine, and progesterone are agents with neuroprotective potential that have

recently undergone clinical investigations or are still under study. In 2014, two large phase III trials of progesterone use in TBI failed to show benefit.^{211,212} Rather than seeking the “silver bullet” of one agent targeting multiple mechanisms, it may be better to consider combining agents with complementary targets and effects.²¹³ Fundamental to any neuroprotective strategy would be the correct detection and tracking of pathophysiologic processes occurring in individual patients, which would provide better evidence for combining or sequential administration of neuroprotective agents.²⁰⁵

Strategies Promoting Cell Survival and Regeneration

Strategies to promote cell survival and regeneration include cellular replacement, gene therapy, and administration of trophic factors. These are aimed at promoting regeneration and neuroplasticity and may ultimately improve functional recovery.^{214,215} The potential of these novel approaches is strengthened by promising experimental and clinical results obtained in neurodegenerative diseases, including Parkinson disease, Huntington disease, and strokes.²¹⁵⁻²¹⁸ This approach is the focus of large research efforts, which will provide possibilities to further improve long-term outcome.

KEY POINTS

1. Successful care for the neurosurgical patient requires excellent collaboration among the anesthetist, neurosurgeon, and intensivist. The results of a technically perfect operation can be ruined by inadequate postoperative care, and a complex operative procedure requires expert intensive care to correct abnormalities in homeostatic mechanisms, ensure adequate cerebral perfusion and oxygenation, and promote recovery of brain function.
2. Specific care and monitoring of the postoperative neurosurgical patient require accurate knowledge of the preoperative situation and the intraoperative procedure, including the surgery, anesthesia, and any surgical complications or difficulties.
3. The principal goal of postoperative neurosurgical intensive care is early detection and treatment of postoperative complications. The second goal is to prevent second insults, which may initiate

or exacerbate secondary damage in a vulnerable central nervous system.

4. The goal of cardiovascular and respiratory monitoring is to ensure adequate hemodynamic and respiratory function, which is essential for optimization of cerebral oxygenation. The driving force here should be formed by cerebral parameters, rather than simply keeping systemic parameters within normal ranges. Invasive arterial BP monitoring is recommended with the reference point set at the same level as the intracranial pressure measurement to allow accurate calculation of the cerebral perfusion pressure.
5. The development of cerebral herniation (tentorial herniation or cerebellar tonsillar herniation) constitutes a neurosurgical emergency. Rapid intervention is required prior to further investigations to determine the cause.

Consensus summary statement of the International Multidisciplinary Consensus Conference on Multimodality Monitoring in Neurocritical Care: a statement for healthcare professionals from the Neurocritical Care Society and the European Society of Intensive Care Medicine. *Intensive Care Med* 2014;40(9):1189–1209.

This manuscript summarizes available evidence and clinical opinions on several aspects of modern monitoring tools in neurocritical care patients. Evidence is graded and reviewed, and clinical applications are critically evaluated, with a focus on the importance of combining clinical, instrumental, and imaging data.

- McNeill L, English SW, Borg N, Matta BF, Menon DK. Effects of institutional caseload of subarachnoid hemorrhage on mortality: a secondary analysis of administrative data. *Stroke* 2013;44:647–652.

This paper, based on administrative data from 25 United Kingdom centers, explores the relationship between caseload and mortality in SAH in over 23,000 patients. Each 100-patient increase in annual patient volume was associated with a 24% reduction in mortality (adjusted mortality ratio, 0.76; 95% confidence interval, 0.67–0.87). This relationship was consistent across the entire range of annual institutional caseloads examined (29–367 cases for the lowest and highest volumes seen in a single center in 1 year).

- Oddo M, Schmidt JM, Carrera E, et al. Impact of tight glycemic control on cerebral glucose metabolism after severe brain injury: a microdialysis study. *Crit Care Med* 2008;36:3233–3238.

Observational prospective cohort of 20 neurocritical care patients monitored with cerebral microdialysis. A total of 2131 cerebral microdialysis samples were analyzed: tight systemic glucose levels were associated with lower cerebral microdialysis glucose levels and increased episodes of brain energy crises. This correlated with increased mortality. Thus, intensive insulin therapy may impair cerebral glucose metabolism after severe brain injury.

In this chapter we outline the epidemiology, presentation, course, and management of key disorders in pediatric neurointensive care. Critically ill infants and children with a compromised central nervous system (CNS) are complex patients and are often highly vulnerable to secondary brain injury. Minimizing physiologic derangements and optimizing therapy are essential from the scene of trauma through the pediatric intensive care unit (ICU). In most cases, transport to a specialized pediatric facility is desirable. Trained specialists in pediatric critical care medicine, pediatric neurologic surgery, and child neurology should deliver the ICU care to these infants and children, with appropriate pediatric ancillary support. The information provided in this chapter is germane to practitioners involved in stabilization, emergency treatment, and transport and to pediatric subspecialists at the tertiary care centers. Recommendations in the areas of trauma (head and spinal cord injury) are addressed in Chapter 56. Neurointensive care issues relevant to the field of neonatology are outside the scope of this chapter; specialized textbooks and reviews in this area should be sought for information in that field.

■ ISSUES UNIQUE TO PEDIATRICS

Two key factors contribute to the unique nature of the practice of pediatric neurointensive care: differences in the specific insults to the CNS in infants and children versus adults and age-related differences in the response to these insults.

Central Nervous System Insults in Infants and Children

Unlike in adults, atherosclerotic vascular disease resulting in stroke, intracerebral hemorrhage, and cardiopulmonary arrest plays little role in pediatric neurointensive care. For example, cardiopulmonary arrest in infants and children results primarily from asphyxia rather than myocardial infarction. Similarly, traumatic brain injury (TBI) in infants younger than 2 years of age is largely the result of abusive head trauma (shaken baby syndrome, child abuse). Unique issues in victims of child abuse, such as chronic injury or delay in presentation, contribute to important differences in diagnosis, treatment, and outcome. The specific CNS insults relevant to pediatric neurointensive care include TBI and spinal cord injury, cardiopulmonary arrest, status epilepticus, stroke, critical CNS infections, postoperative neurosurgical conditions, and several other less common disorders. (Traumatic brain and spinal cord injury are addressed in Chapters 56 and 57.)

Age-Related Differences in the Response to Central Nervous System Insults

Brain Water and Blood-Brain Barrier

Many biochemical, physiologic, and physical factors exhibit large fluctuations during brain development. Although the magnitude of these changes are most dramatic during prenatal development, they may contribute to age-related differences in response to critical CNS disorders.^{1,2} Large decreases in brain water content occur throughout postnatal development into adult life.³⁻⁵ These changes are global and correlate with the degree of myelination. The impact of these changes on edema formation after brain injury is unclear; however, the rapid

and diffuse cerebral swelling phenomenon described in many CNS insults in infants and children may be related to this high water content in the immature brain. This is suggested by studies showing that parenchymal injection of glutamate into the immature (but not adult) rat brain rapidly produces a large area of edema.⁶ The rapidity of development and the great magnitude of edema may result in part from rapid diffusion of glutamate and other mediators through the immature brain. In contrast to the changes in brain water during development, there is little contemporary evidence to support similar changes in blood-brain barrier permeability^{7,8} or enhanced vulnerability of the barrier to insults such as ischemia or trauma.⁹ Blood-brain barrier permeability after CNS insults has received little study in pediatric patients.

Cerebral Blood Flow and Energy Metabolism

Postnatal changes in cerebral blood flow (CBF) and energy metabolism have been reported in numerous mammalian species including humans.¹⁰⁻¹⁷ In all cases, CBF is quite low both before birth and during infancy, rapidly increases to a peak during childhood, and then decreases to a plateau with a gradual decline with increasing age during adulthood. In a study of 42 normal infants and children, cortical CBF in newborns was between 30 and 45 mL/100 g/min—lower than that reported in adults. In contrast, cortical flow in children between the ages of 5 and 6 years was between 50% and 85% higher than in adults. CBF decreased to adult values by about age 15 years (Fig. 60-1).^{18,19} Increased CBF in children (versus either adults or infants) corresponds to the period of maximal postnatal brain growth, specifically, maximal increases in the number of synapses.²⁰⁻²² Similarly, the cerebral metabolic rate for glucose is maximal in children between the ages of 3 and 9 years.¹⁵ The impact of these factors in CNS injury is poorly understood. Hyperemia has been implicated as an important facet of the pathophysiology of pediatric CNS injury. Because the level of CBF in the normal child is greater than in adults, the frequency of hyperemia in children is probably lower than has been suggested. Hyperemia in most gray matter structures in children between the ages of 3 and 10 years should probably be based on a flow value greater than about 70 mL/100 g/min^{17-19,22} rather than the value of about 45 mL/100 g/min suggested for adults.²³ Alterations in metabolic demands after injury must also be considered. Recent studies in both developmental brain injury models and children after cardiac arrest have demonstrated regional hyperemia.^{24,25} In children, the combination of hyperemia with a reduced apparent diffusion coefficient on MRI after cardiac arrest was associated with an unfavorable outcome.²⁵

Cerebral Perfusion Pressure

Cerebral perfusion pressure (CPP = mean arterial blood pressure – intracranial pressure [ICP]) is a critical determinant of CBF outside the limits of autoregulation or when autoregulation of blood pressure (BP) is disturbed. In adults, the normal limits of autoregulation are generally accepted to be between 60 and 150 mm Hg.^{26,27} Based on studies in normal immature animals, the lower limit for BP autoregulation of CBF is directly related to age.²⁸⁻³⁰ This is anticipated, since CPP is a function of arterial blood pressure, which is dependent on age. Few data are available on normal values for CPP in infants and children. A mean value of 37.5 ± 4.9 mm Hg (\pm SD) was reported in normal preterm infants.³¹ The lower limit of BP autoregulation was not

FIGURE 60-1 ■ Mean (curve) and ± 1 SD (pink area) for normal cerebral blood flow in 42 children from 2 days to 19 years of age, compared with adult values (dashed line). Compared with adult values, cerebral blood flow is lower in infancy, but thereafter values throughout childhood exceed those of adults. (From Chiron C, Raynaud C, Maziere B, et al. Changes in regional cerebral blood flow during brain maturation in children and adolescents. *J Nucl Med*. 1992;33:696-703. Reprinted by permission of the Society of Nuclear Medicine.)

determined. There are also limited data available on the lower limit of BP autoregulation of CBF in brain-injured infants and children. Vavilala et al.³² studied CBF autoregulation in 53 healthy infants and children. Surprisingly, the lower limit of autoregulation was between 50 and 60 mm Hg across the age groups of younger than 2 years, 2 to 5 years, 6 to 9 years, and 10 to 14 years. This suggests that there is less autoregulatory reserve (the difference between baseline MAP and the lower limit of autoregulation) in infants and young children than in older children or adults. It suggests that modest BP reductions in infants with severe TBI could compromise CBF. This may help explain the important deleterious effects of hypotension as a side effect in pediatric TBI.³³ It suggests that a lower limit for CPP in brain-injured infants and young children of ~50 mm Hg might be wise. Recent studies by Chambers et al.³⁴ and Allen et al.³⁵ in pediatric TBI suggest age-related targets. Chambers et al.³⁴ suggest values of 53, 63, and 66 mm Hg for children 2 to 6, 7 to 10, and 11 to 16 years of age, respectively. Allen et al.³⁵ suggest values of 40, 50, and 50-60 for children 0 to 5, 6 to 17, and >17 years of age, respectively. However, the impact on outcome of inducing mild hypertension in this setting remains to be studied.

Myelination

In humans, considerable myelination occurs during postnatal life.²¹ The impact of this process on the age-related response to pediatric CNS injury is not known but has been suggested by many to contribute to enhanced plasticity in the pediatric brain. White matter injury is common after CNS insults in children such as TBI.³⁶

Excitotoxicity

Increases in brain interstitial concentrations of excitatory amino acids such as glutamate are part of a fundamental response to CNS insults across all ages.³⁷⁻⁴² Excitotoxicity-mediated damage after brain injury is also suggested in clinical reports in children.^{37,40-42} There are important age-dependent facets of excitotoxicity. At several periods in development, large numbers of excitatory amino acid receptors are produced, and these periods correlate temporally with increased synaptic plasticity.^{38,39} Experimental data suggest that the immature brain is at great risk for excitotoxicity.^{38,39} Excitotoxicity may trigger neuronal death via multiple pathways (necrosis, apoptosis, necroptosis, and autophagy among others).⁴³ Extrasynaptic *N*-methyl *D*-aspartate receptors may be important.⁴³ Hypothermia may target this pathway in part, but an optimal pharmacologic agent remains elusive here.

Apoptosis

Experimental models and human data have made it increasingly clear that cells dying after CNS insults can be categorized on a morphologic continuum from necrosis to apoptosis.⁴⁴⁻⁴⁶ The importance of balanced apoptosis (or programmed cell death) in embryogenesis, as well as reports examining apoptosis in experimental TBI, suggest that there may be important age-related differences in the cell death cascades in response to traumatic or ischemic brain injury.⁴⁷ For example, neurons in developing animals appear to be more vulnerable to apoptosis than those in mature animals.^{44,47} Also, physiologic levels of excitatory amino acids are necessary for neuronal survival in the developing brain.⁴⁸ These data, including studies in primates,⁴⁹ raise concern about the ability of therapies such as barbiturates, ketamine, propofol, or inhibitors of excitatory amino acid receptors to actually induce neuronal death during development. What remains unclear, however, is if this enhanced apoptotic response is limited to prenatal development or if it is important during treatment of infants and children in the pediatric ICU. Nevertheless, an important role for apoptosis in pediatric brain injury is suggested by the fact that analysis of cerebrospinal fluid (CSF) in infants and children with severe TBI has provided some of the most compelling molecular data for the participation of these pathways in humans.² These data include participation of death effectors such as cytochrome-c and Fas receptor/ligand interactions and failure of antiapoptotic pathways in infants and children with poor outcome after severe brain injury.^{2,50-53} How these findings will influence our therapies remains to be determined, but they suggest that apoptotic neuronal death may represent a particularly important therapeutic target in pediatric neurointensive care.

Mitochondria Failure and Oxidative Stress

It is well known that the developing brain exhibits enhanced vulnerability to oxidative stress, in part related to deficiency of glutathione peroxidase.⁵⁴ Recent studies in developmental models of TBI and cerebral ischemia have demonstrated an important role of mitochondria in initiating the oxidative stress that is seen in these two insults.^{55,56} Mitochondrial targeting therapies may thus be important to develop for clinical trials,^{55,56} since clinical studies in TBI have confirmed a marked depletion of antioxidant defenses in infants and children.⁵⁷

Extracerebral Factors

Many extracerebral factors play a role in the age-related differences in the response to critical CNS disorders. Age-related differences in the response to hypoxemia-ischemia and hypotension are the prototype examples.

Hypotension and hypoxemia are the two most important secondary insults in patients with critical CNS disorders. Hypotension is the most important extracerebral factor associated with poor outcome after severe TBI.⁵⁸ This may contribute to the reported high mortality rate (62%) in this condition in children younger than age 4 years.⁵⁹ Nearly 50% of these children present with shock, versus only 30% of adults.⁵⁹ The limited blood volume of infants and young children make relatively small amounts of blood loss from scalp lacerations or other foci important. In contrast, the immature brain and cardiovascular systems are resistant to hypoxic-ischemic insults compared with mature individuals.⁶⁰ The duration of asphyxia resulting in cardiac arrest is inversely related to age.⁶¹⁻⁶⁴ Resistance to asphyxia-induced cardiac arrest in the immature individual, however, could have complex effects. For example, children may survive protracted episodes of hypoxemia and hypotension that would be lethal in adults. Resistance of the immature myocardium to asphyxia does not preclude the development of cerebral damage from hypoxemia, because between 25% and 56% of children who suffer asphyxia without cardiac arrest have poor neurologic outcomes.⁶⁵ This might also explain some of the severe pathology seen in infants after abusive head trauma, in which apnea, seizures, and agonal states occur.⁶⁶ Ichord et al.⁶⁷ showed that a hypoxic-ischemic injury pattern was commonly seen on diffusion-weighted magnetic resonance imaging (MRI) in victims of abusive head trauma. Similarly,

Berger et al.⁶⁸ showed that the serum biomarker profile of neuron-specific enolase in infants with abusive head trauma was more similar to that seen in children with asphyxia than TBI.

SPECIFIC DISEASES OR CONDITIONS

Cardiopulmonary Arrest

Cardiopulmonary arrest in adults is addressed in detail in Chapter 50. Although some of that chapter is germane to pediatric patients, the importance of asphyxia as the etiology in children mandates a separate discussion.

Epidemiology

The causes of cardiopulmonary arrest in childhood are heterogeneous. Causes of arrest in the prehospital setting include trauma, sudden infant death syndrome, poisoning, and respiratory distress secondary to drowning, choking, severe asthma, or pneumonia.⁶⁹ Traumatic arrest secondary to exsanguination, massive head injury, or airway compromise is the leading cause of death in childhood and young adulthood. Nontraumatic arrest typically occurs as a consequence of hypoxemia and hypercarbia, leading to respiratory arrest, bradycardia, and ultimately asystole or pulseless electrical activity.⁶⁹⁻⁷¹ Ventricular tachycardia or fibrillation occurs less commonly in children than adults, but it is not rare; 5% to 15% of children with prehospital arrest have these rhythms.⁷²⁻⁷⁴ About 50% of arrests in the prehospital setting occur in previously healthy patients, whereas most in-hospital arrests occur in children with preexisting medical conditions.⁷⁵ Children with special healthcare needs are especially vulnerable to acute deterioration.

Outcome

The rate of survival of pediatric cardiopulmonary arrest is about 13%, with survival of in-hospital arrest greater than that of prehospital arrest (24% versus 9%).⁷¹ Patients with asystole have the lowest rate of survival (~5%), whereas survival is higher in patients with ventricular fibrillation or ventricular tachycardia (~30%). Patients presenting with isolated respiratory arrest have the highest rate of survival (~75%).^{76,77} Witnessed arrest and bystander cardiopulmonary resuscitation (CPR) are associated with survival, whereas CPR of greater than 30 minutes and administration of more than two doses of epinephrine are associated with a poor outcome.^{69,72,78,79} About 60% of survivors will have good neurologic outcome, with the remainder showing severe disabilities. Intermediate outcomes are uncommon. Accurate prediction of poor outcome can enable withdrawal of support and decrease the possibility that children are rescued to survival but in a neurologically devastated state.^{80,81} Predictors of poor outcome in children include remaining comatose at 24 hours, a Glasgow Coma Scale (GCS) score of less than 5, absence of spontaneous respirations, absence of pupillary reflex, and specific abnormalities found on electroencephalography (EEG) or after testing of somatosensory evoked potentials. Predictors of poor outcome should be applied with caution to children suffering cardiopulmonary arrest caused by drug overdose or hypothermic exposure (ice-cold water drowning), in which good outcomes have been reported in some cases after even prolonged durations of arrest.

Treatment

The optimal treatment of pediatric cardiopulmonary arrest is prevention. If cardiopulmonary arrest occurs, the most important first step is to provide immediate CPR. Many infants and children, especially in the prehospital setting, will be rescued solely by the administration of CPR.⁶⁹ Important differences are emerging in resuscitation of adults versus children with cardiac arrest. Although there has been a general movement toward bystander compression-only CPR in adults, Kitamura et al.⁸² compared conventional versus compression-only CPR in over 5000 children in Japan. In arrests of noncardiac origin, both survival and favorable neurologic outcomes were better in children given conventional CPR. In addition, outcomes were similar in

FIGURE 60-2 ■ Two-person technique for cardiopulmonary resuscitation in infants and young children. (Reprinted from Pediatric Basic Life Support. Guidelines 2000 for Cardiopulmonary and Emergency Cardiovascular Care: International Consensus on Science. Circulation. 2000;102(Suppl):I253-290.)

the setting of arrests of cardiac origin. This study strongly suggests that the lay public should be taught conventional CPR for all children who suffer cardiac arrest. A recent large study in adults also showed that continuous compressions did not lead to higher survival or better outcomes than did the use of chest compressions with interruption for ventilation.⁸³ In addition, the technique for compressions in children is different than in adults. Only one hand is used to deliver chest compressions to children younger than age 8 years. Two methods are approved for delivering chest compressions to infants. When two or more rescuers are available, one rescuer provides chest compressions by encircling the chest with two hands and depressing the sternum with both thumbs while the other rescuer provides ventilation (Fig. 60-2). When only one rescuer is present, two fingers from one hand are used to provide chest compressions, and the other hand is used to maintain the head-tilt. Providing adequate ventilation is especially important for children, because most pediatric arrests are secondary to airway compromise. In contrast, adults frequently suffer from cardiac causes of arrest and require intensified efforts at providing chest compressions and early defibrillation. Thus, the recommended ratio of chest compressions to ventilations for young children is 5:1, compared with a ratio of 15:2 for older children and adults. Once the patient is intubated, ventilations should be asynchronous. Although ventricular fibrillation and ventricular tachycardia are uncommon in children, survival with this rhythm is high (about 30%), so cardiac rhythm should be ascertained as early as possible.⁷¹ Automated external defibrillators that can deliver a 50-J dose are now available and are appropriate for use in children aged 1 to 8 years.⁸⁴

Intubation of pediatric patients is a difficult task for inexperienced providers. Furthermore, the short length of the trachea combined with patient movement during transport and patient care can easily result in displacement of the tracheal tube.⁸⁵ Secondary confirmation of tracheal tube placement is critical. End-tidal CO₂ detection is the method most commonly utilized for secondary confirmation of tracheal tube placement in children. However, a false-negative reading can occur when circulatory collapse is so severe that CO₂ is not delivered to the alveolar space. If CO₂ is not detected during CPR, tube placement can be confirmed by visualizing the airway with a laryngoscope. Although no single confirmation technique is 100% reliable in all circumstances, some effort of secondary confirmation of tube placement can be helpful.

Patients are initially resuscitated using 100% oxygen. The rationale is that hypoxia often causes or contributes to the development of cardiac arrest, and an oxygen debt accumulates during cardiac arrest. However, there is increasing awareness that oxygen might contribute to reperfusion injury, and thus *prolonged* delivery of *unnecessarily* high concentrations of oxygen should be avoided.^{86,87}

Adults resuscitated from cardiac arrest demonstrate intact cerebrovascular CO₂ reactivity with evidence of hyperventilation-associated ischemia.⁸⁸ Although there is evidence that the injured brain has diminished metabolism, which may offset the decrease in blood flow,

it seems prudent to avoid decreasing CBF to the injured brain. Therefore, hyperventilation should be reserved for patients with signs of cerebral herniation syndrome or suspected pulmonary hypertension. It is also prudent to guard against inadvertent hyperventilation during patient transport.⁸⁹ Increased use of quantitative continuous CO₂ monitors throughout the health care system would decrease the occurrence of inadvertent hyperventilation.

Establishing vascular access in children can be challenging. Fortunately, intraosseous access can be achieved within 30 to 60 seconds and provides a route for drug and fluid administration when intravascular access cannot be readily achieved. Drugs including lidocaine, epinephrine, atropine, and naloxone (mnemonic LEAN) can be administered through the tracheal tube. Optimal doses for drugs given via the tracheal tube are not established, but the recommended dose of epinephrine is 0.1 mg/kg (10 times the intravenous [IV] dose). A bedside glucose measurement should be obtained, and if hypoglycemia is present, it should be treated with 0.5 to 1 g/kg of IV glucose. There is experimental evidence that hyperglycemia and hypoglycemia exacerbate ischemic injury. Thus, euglycemia is desirable. Initial resuscitation fluids should be limited to isotonic crystalloid solutions such as normal saline or lactated Ringer's solution.

The most commonly used drugs in pediatric resuscitation are epinephrine, atropine, and sodium bicarbonate (Table 60-1). Magnesium and calcium are reserved for specific indications such as torsades de pointes, hypocalcemia, and calcium channel blockade. Amiodarone has recently been added to the American Heart Association (AHA) pediatric algorithms, based on extrapolation from experience with adults.⁹⁰ Adults with ventricular fibrillation or ventricular tachycardia in the prehospital setting are more likely to be successfully defibrillated after IV administration of amiodarone compared with lidocaine.⁹¹ Accordingly, amiodarone (5-mg/kg bolus) is a therapeutic option for children with pulseless arrest. Amiodarone (5 mg/kg infused over 20 to 60 min) is also an option for ventricular tachycardia with a pulse but should be used with extreme caution because of the risk for profound hypotension. Vasopressin has been added to the AHA adult algorithms as an alternative to epinephrine on the basis of its improved myocardial and CBF effects. However, subsequent clinical data in adults have not consistently yielded positive results, and pediatric data are limited to small case series.^{92,93} The optimal vasopressor for hemodynamic support after return of circulation in children is not known.

Extracorporeal membrane oxygenation (ECMO) has been used to successfully resuscitate children from selected causes of in-hospital cardiac arrest.⁹⁴⁻⁹⁸ ECMO-CPR provides greater cerebral and myocardial blood flow than either closed- or open-chest CPR and facilitates titration of temperature, blood flow, and oxygen-carrying capacity.

Good outcomes have been documented with the use of ECMO even when initiated after durations of conventional CPR typically associated with poor outcomes. It is best reserved for patients with reversible conditions or as a bridge to cardiac transplantation.

Post-resuscitative Care

Temperature control is a priority for patients who remain comatose after cardiac arrest. In investigations carried out a decade ago, adults cooled to 32°C to 34°C for 12 to 24 hours after resuscitation from ventricular fibrillation demonstrated improved survival and neurologic outcome.⁹⁹ However, recent investigations suggest that targeted temperature management at 36°C may be as beneficial as 32°C to 34°C.¹⁰⁰ In contrast, fever worsens outcome in experimental models of brain injury and has been associated with worse clinical outcome in adults with ischemic brain injury. Children resuscitated from cardiac arrest often develop mild hypothermia followed by delayed fever.¹⁰¹ There is a consensus that initial hypothermia, if tolerated, should be permitted to continue and fever should be vigilantly avoided. The practice of inducing hypothermia in normothermic children is more controversial. Clinical trials of induced hypothermia for neonatal asphyxia have been remarkably positive,¹⁰²⁻¹⁰⁴ and important data in newborns with asphyxia indicate that even one degree of hyperthermia after the insult is associated with neurologic morbidity.¹⁰⁵ The recent therapeutic hypothermia after cardiac arrest (THAPCA) trial for out-of-hospital arrests in children did not reveal a significant benefit for cooling for 48 hours after cardiac arrest in children.⁷⁵ However, the study was underpowered and suggested trends toward improved outcomes and reduced mortality by hypothermia, and some have advocated for its use based on the results of this trial.¹⁰⁶

During recovery from global ischemia, there may be a period of prolonged, multifocal, decreased CBF. Hypotension and hypoxia should be avoided during this period to prevent development of a secondary brain injury. As previously mentioned, the optimal regimen of oxygen and pressor therapy is not known and requires further study.

Sustained elevation of ICP may be more common after asphyxial arrests versus arrests of cardiac origin¹⁰⁷ and is a poor prognostic sign in children with drowning. ICP monitoring fell out of favor in the 1980s when it was found not to influence outcome in small case series.¹⁰⁸ However, studies using contemporary ICP-directed therapy (perhaps including induced hypothermia) deserve reevaluation.

Miscellaneous

Most pediatric victims of cardiopulmonary arrest will not be successfully resuscitated. The difficulty of accepting this reality often results in prolonged attempts at resuscitation. The AHA guidelines state, "In

TABLE 60-1 Drugs Commonly Used in Arrest or Peri-arrest Conditions

| DRUG | DOSE | MAXIMUM SINGLE DOSE | ROUTE |
|------------------------------|-------------------------------------|---------------------------------------|---|
| Adenosine* | 0.1 mg/kg Repeat dose: 0.2 mg/kg | 12 mg | IV (rapid push) |

the absence of recurring or refractory ventricular fibrillation or ventricular tachycardia, history of a toxic drug exposure, or a primary hypothermic insult, resuscitative efforts may be discontinued if there is no return of spontaneous circulation despite advanced life support. In general, this requires no more than 30 minutes.⁹⁰ This acknowledges the futility of prolonged resuscitative efforts and empowers clinicians to feel *permitted to stop* resuscitative efforts. The guideline does not mandate stopping at a specific duration of CPR, but clinicians should recognize that the chance of survival with lifelong severe disabilities correlates with the duration of CPR, although prolonged CPR may benefit some children.

Surveys indicate that most family members would like to be present during resuscitation attempts of a loved one¹⁰⁹⁻¹¹²; presence during resuscitation can help family members adjust to the death.^{113,114} Although allowing family presence during resuscitation requires planning and additional resources, when done properly it is worth the effort.

Status Epilepticus

Status epilepticus is a pediatric emergency traditionally defined as either a continuous seizure of at least 30 minutes or more than two discrete seizures without complete recovery of consciousness. *Refractory status epilepticus* is defined as failure of two first-line antiepileptic medications to treat this condition for greater than 60 minutes. Many children with refractory status epilepticus have new or established CNS lesions.¹¹⁵

Epidemiology and Etiology

The incidence of pediatric status epilepticus from a prospective, population-based study is 40 cases/100,000 per year. Infants younger than 1 year of age have the highest incidence at 150 cases/100,000 per year.¹¹⁶ More than 90% of cases are convulsive status epilepticus. The first episode of status epilepticus occurs at a mean age of 4.2 years.¹¹⁷ There is a slight male predominance in status epilepticus.^{116,118}

There are five etiologic categories of status epilepticus that have a bearing on treatment and prognosis. A child with *idiopathic or cryptogenic* status epilepticus has no prior history of seizures and no known risk factors. *Atypical febrile* status epilepticus occurs during fever in children with no prior history of seizures without fever. Children with *acute symptomatic* status epilepticus have new CNS lesions such as encephalitis, trauma, tumor, stroke, or anoxia. Children with *remote symptomatic* status epilepticus have preexisting CNS lesions and therefore a lowered seizure threshold. In these children, status epilepticus can occur without provocation, sometimes even years after the initial insult. Finally some children have status epilepticus resulting from *progressive encephalopathy*, including neurodegenerative diseases, malignancies, and neurocutaneous syndromes (Box 60-1).^{116,118,119}

In one study, status epilepticus accounted for 1.6% of total pediatric ICU admissions, and etiology varied with age. In children younger than 2 years of age, *acute symptomatic* status epilepticus from meningitis and encephalitis accounted for 51% of cases, whereas *remote symptomatic* status epilepticus in children with a prior diagnosis of epilepsy was seen in 16% of children. Older children were more likely than younger children to have a history of epilepsy.¹¹⁸ Mortality rates for status epilepticus in children are between 3% and 6%.^{116,119} Mortality is dependent on etiology, age, and duration of status epilepticus. Mortality rates of 0% and 12.5% were seen when patients were divided into either unprovoked or febrile status epilepticus versus acute CNS insult or progressive encephalopathy groups, respectively.¹²⁰ Morbidity risk varies from 11% to 25%. Infants are at great risk for morbidity because the etiology in this group is commonly *acute symptomatic* status epilepticus. Neurologic sequelae of status epilepticus include epilepsy, recurrence, mental retardation, and motor disorders. However, many of the morbidities can be attributed to the underlying disease and not status epilepticus per se. Risk of recurrence in the category of *idiopathic* status epilepticus is less than 5%. In contrast, recurrence of status epilepticus in children in the *acute symptomatic* groups can be as high as 60%.^{116,120} Systemic complications occur with increasing frequency in

proportion to the duration of status epilepticus, the most important being respiratory failure, cardiovascular compromise, and autonomic and metabolic disturbances.¹²¹

There has also been considerable interest in the importance of diagnosis and treatment of subclinical status epilepticus that is commonly seen in children with neurologic insults requiring critical care, such as cardiac arrest and TBI, and is associated with an unfavorable outcome.^{122,123}

Diagnosis

As indicated, status epilepticus can be convulsive or nonconvulsive, the latter perhaps seen only on EEG. Convulsive seizures either begin as generalized seizures or progress from partial seizures. Nonconvulsive seizures are characterized as having subtle clinical signs such as nystagmus, irregular clonic twitches along with decreased consciousness, and/or ictal discharges on EEG. Included under the subheading of nonconvulsive seizures are complex and simple partial and absence seizures.¹²⁴

Treatment

The goals in treating status epilepticus are to provide respiratory and cardiovascular support, terminate clinical and electrical seizure activity, identify and treat precipitating factors, and prevent systemic complications.¹²⁴ Recognizing that a prolonged duration of seizure increases the risk of morbidity and mortality, recent guidelines and international surveys support initiating antiepileptic drugs for treatment within 5 minutes after the onset of an episode of status epilepticus. IV lorazepam is the recommended first-line therapy.^{125,126} A timetable for treatment of status epilepticus in children is provided in Table 60-2.

History of present and past illness may be useful in determining the cause of status epilepticus and in choosing therapy, but obtaining the history should not delay resuscitation. Initial treatment includes basic life support—airway, breathing, and circulation (ABCs). Prevention of hypoxemia and hypotension, which exacerbate neuronal injury, is important. The airway should be kept open with simple maneuvers and 100% oxygen applied with a nonbreathing mask. The airway should also be kept clear of secretions. Efficacy of oxygenation efforts should be monitored by pulse oximeter. Ventilation efforts are assessed clinically or by arterial blood gas determinations. If the patient is unable to maintain adequate oxygenation or ventilation, tracheal intubation using a rapid sequence technique is indicated. Circulation is monitored by assessment of ECG, BP, and perfusion. Ideally, a large-bore peripheral IV catheter should be placed for fluid and drug administration. A bedside blood glucose determination should be obtained. Serum electrolyte levels, renal and liver function tests, and anticonvulsant levels should be assessed. A serum and urine toxicology screen should be obtained. Fever and hypoglycemia should be treated as quickly as possible. The neurologic examination follows, focusing on

TABLE 60-2 Suggested Timetable for Emergency Diagnosis and Treatment of Status Epilepticus

| TIME | EXAM/INTERVENTION | TESTING |
|--|--|---|
| Initial presentation: 0 min | Airway, breathing, circulation, IV access, monitoring | Glucose, oxygenation via pulse oximetry \pm blood gas analysis |
| Primary survey: 5 min | Neurologic exam Administer antiepileptic drugs Lorazepam, 0.1 mg/kg IV Phenobarbital, 20 mg/kg IV Normal saline maintenance IV Reduce fever | Electrolytes, renal and liver function, ammonia, anticonvulsant levels, toxicology, complete blood cell count, urinalysis |
| Secondary survey: 15-30 min | Evaluate treatment results Second-line antiepileptic drug if seizure persists Fosphenytoin, 20 mg/kg IV, or phenytoin, 20 mg/kg IV | Patient-specific: cranial imaging (CT vs. MRI), lumbar puncture, EEG, ECG |
| Status epilepticus: >30 min | Intubation and mechanical ventilation | |
| Refractory status epilepticus: >60 min | Titrate antiepileptic drug to burst suppression Pentobarbital, 10 mg/kg IV given over 30 min, then 5 mg/kg every hour for 3 doses, then 1 mg/kg/h; titrate to effect Midazolam, 0.15 mg/kg IV, then 1-2 μ g/kg/min, titrate to effect Phenobarbital, 5-10 mg/kg IV every 20 minutes to achieve burst suppression, then every 12 hours Evaluate need for vasopressors | Continuous EEG Neurologic consultation Consider anesthesia consultation for treatment with inhaled anesthetic |

CT, computed tomography; ECG, electrocardiogram; EEG, electroencephalogram; IV, intravenous; MRI, magnetic resonance imaging.

GCS score, signs of raised ICP, focal deficits, and pupil size. In patients receiving neuromuscular blockade, electrical seizure activity should be monitored with continuous EEG.

First-line antiepileptic drugs for pediatric status epilepticus include benzodiazepines, phenytoin or fosphenytoin, and phenobarbital. Drug choice depends on the route available (IV is preferred), the patient's maintenance anticonvulsants (a different class is recommended), and patient characteristics. Evidence-based studies of anticonvulsants in children are rare. Recommendations are extrapolated from studies in adults. The optimal first-line treatment of status epilepticus in children is controversial.

As previously indicated, guidelines for the management of status epilepticus recommended IV lorazepam as the preferred first-line agent¹²⁵ for emergent initial therapy. Also, in an emergency, midazolam can be given IM or diazepam rectally.¹²⁵ Lorazepam can be administered rapidly, has a long duration of effect, and is effective even when administered rectally. Lorazepam produced less respiratory failure requiring intubation than diazepam in retrospective¹²⁷ and prospective studies.¹²⁸ The incidence of respiratory depression in these studies varied widely—between 3% and 76%. Support for selection of lorazepam over diazepam was also shown in a recent Cochrane review.¹²⁹

For subsequent urgent control, fosphenytoin or phenobarbital are reasonable choices, along with IV valproate, levetiracetam, or a continuous infusion of midazolam.¹²⁵ In a study in adults comparing lorazepam, phenytoin, phenobarbital, and diazepam, phenytoin had the highest success rate in stopping status epilepticus.¹³⁰ Phenytoin is not commonly associated with respiratory depression and produces less impairment of consciousness than either benzodiazepines or barbiturates. Fosphenytoin has the advantage of having a faster infusion rate, shorter onset of action, and fewer cardiovascular side effects than phenytoin but is more expensive.

Phenobarbital is also a very effective anticonvulsant, but it is often not the first choice in the treatment of status epilepticus because of its side effects of respiratory depression and cardiovascular disorders, especially when used in combination with benzodiazepines. Infants metabolize phenobarbital more rapidly than older children and often require higher doses adjusted for body weight. Nevertheless, the pharmacokinetics of phenobarbital are more predictable than those of phenytoin in infants.

Additional Diagnostic Workup

Lumbar puncture is best performed early after presentation, but not in unstable patients or those who may have increased ICP or coagulopathy or thrombocytopenia. The decision to perform lumbar puncture should be guided by head computed tomography (CT). Otherwise, the type of neuroimaging used in infants and children with status epilepticus should be individualized, depending on history and physical findings. Both ECG and EEG are useful to investigate the cause of status epilepticus (e.g., long QT syndrome or identifiable EEG patterns). EEG is also useful in titrating therapy (see the next section).¹²⁴

Drug Treatment for Refractory Status Epilepticus

Refractory status epilepticus is generally considered to be present when a patient fails treatment with a benzodiazepine and one other antiepileptic drug. This diagnosis is made with either EEG or clinical observation. Treatment should then proceed. Monitoring in a pediatric ICU or intermediate unit is recommended and neurologic consultation should be considered. These patients are mechanically ventilated, and seizures are typically treated with a variety of therapies, generally to induce burst suppression on continuous EEG. Most commonly, pentobarbital is used as a continuous infusion to treat refractory status epilepticus. Pentobarbital is given initially as a slow IV loading dose of 5 to 15 mg/kg, followed by an infusion rate of 1 mg/kg/h titrated to effect. There are differing opinions on when to begin to wean therapy, but it is generally recommended that about 12 hours of seizure cessation be attained before weaning the infusion.¹³¹ In children, placement of either a central venous pressure or pulmonary artery catheter is indicated to titrate fluid, inotropic, and pressor support. Pentobarbital use often requires the addition of inotropes or pressors. A midazolam infusion has also been shown to be effective in refractory status epilepticus in some children (0.15 mg/kg IV bolus followed by infusion of 1-2 μ g/kg/min). The infusion can be increased every 15 minutes if seizures are still present on continuous EEG or if burst suppression is not achieved. With this approach in one series, inotropic support was not required.¹³² As an alternative to continuous barbiturate or midazolam infusion, phenobarbital can be administered every 20 minutes (5-10 mg/kg IV) to achieve burst suppression and then as a chronic therapy every 12 hours.

Stroke

Epidemiology

Stroke in children is becoming increasingly recognized and now exceeds an incidence of 8 cases per 100,000 children per year.¹³³ Neonates account for about 25% of these cases. The increasing incidence is believed to result from improvements in diagnostic tools (MRI, CT, magnetic resonance angiography [MRA]) applied to the pediatric population and to increasing survival rates in infants and children with stroke risk factors (e.g., complex congenital heart disease, malignancies).

Etiology

Atherosclerosis is a key risk factor for stroke in adults. In pediatric and neonatal stroke, extracerebral risk factors contribute to about 75% of cases, but the spectrum of risk factors differs from those seen in adults. DeVeber¹³³ grouped the most common risk factors for childhood ischemic stroke into vascular, intravascular, and embolic categories (Box 60-2). The most common vascular risk factor has been reported to be transient cerebral arteriopathy.¹³⁴ Post-varicella arteriopathy, migraine, traumatic carotid dissection, vasculitis, and moyamoya syndrome are important examples in this category. Intravascular occlusion can occur in disorders such as sickle cell anemia, sinus thrombosis,

leukemias, and both acquired and congenital prothrombotic states. Dehydration and intravascular volume depletion increase stroke risk in these settings, which are of special importance in the pediatric ICU. There is an 84% incidence of an acute systemic illness and a 30% incidence of dehydration reported in infants and children with cerebral sinovenous thrombosis.¹³⁵ Congenital and acquired heart disease are the most important underlying causes of embolic stroke.¹³³ The risk of stroke in children after surgery for congenital heart disease is about 1 in 250 cases.¹³⁶

Diagnosis

The clinical presentation of stroke in infants and children is age related. Infants typically present with seizures and lethargy, whereas older children may present with acute focal neurologic deficits or diffuse symptoms (headache, lethargy, or seizures).^{133,137} It is often difficult to differentiate migraine, Todd paralysis, and stroke in children. Complicating this problem, CT may be normal within the initial 12 hours.¹³³ MRI is a more sensitive technique for diagnosing stroke, and advanced MRI modalities such as perfusion, diffusion, and MRA are important adjuncts to making the diagnosis. These methods are discussed in Chapter 58. Because of the impact of making a specific vascular diagnosis on the management strategy, angiography is often recommended in children with idiopathic stroke.¹³³

BOX 60-2 Most Common Risk Factors for Childhood Ischemic Stroke

VASCULAR

Arteriopathies

Transient cerebral arteriopathy of childhood
Postvaricella angiopathy
Fibromuscular dysplasia
Moyamoya syndrome
Postradiation vasculopathy

Vasospastic Disorders

Migraine
Ergot poisoning
Vasospasm with systemic arterial hypertension

Vasculitis

Meningitis
Systemic lupus erythematosus
Polyarteritis nodosa
Granulomatous angiitis
Takayasu arteritis
Dermatomyositis
Inflammatory bowel disease
Drug abuse (cocaine, amphetamines)

Systemic Vascular Disease

Early atherosclerosis
Diabetes
Ehlers-Danlos syndrome
Pseudoxanthoma elasticum
Homocystinuria
Fabry disease

Trauma

Brain herniation and arterial compression
Posttraumatic dissection
Intraoral trauma
Carotid ligation (e.g., extracorporeal membrane oxygenation)
Arteriography

INTRAVASCULAR

Hematologic Disorders

Hemoglobinopathies (sickle cell anemia)
Thrombocytosis
Polycythemia
Leukemia or other hematologic neoplasms

Acquired Prothrombotic States

Prothrombotic medications
Pregnancy and the postpartum period
Lupus anticoagulant
Anticardiolipin antibodies
Lipoprotein abnormalities
Hyperhomocysteinemia

Congenital Prothrombotic States

Antithrombin deficiency
Protein S deficiency
Protein C deficiency
Plasminogen deficiency
Factor V Leiden
Prothrombin gene mutation
Methylenetetrahydrofolate reductase

Metabolic Disorders

Hyperhomocysteinemia
Hyperlipidemia

EMBOLIC

Congenital Heart Disease

Complex congenital heart defect
Ventricular/atrial septal defect
Coarctation of the aorta
Patent foramen ovale
Patent ductus arteriosus

Acquired Heart Disease

Rheumatic heart disease
Prosthetic heart valve
Bacterial endocarditis
Cardiomyopathy and myocarditis
Atrial myxoma
Cardiac rhabdomyoma
Cardiac arrhythmia

Trauma

Amniotic fluid or placental embolism
Fat or air embolism
Foreign body embolism
Cardiac catheterization

In addition to cardiac surgery or catheterization, endocarditis, cardiomyopathy, and other occult cardiac abnormalities are important risk factors for embolic stroke. Echocardiography is thus essential in the diagnostic workup for stroke in children.^{138,139} The reader is referred to an outstanding state-of-the-art guidelines approach to the acute management of children with stroke, which was recently published by Rivkin et al.^{140a} and includes description of an emergent diagnostic protocol.

Treatment

In the acute setting, antithrombotic therapy has been increasingly used in the therapy for pediatric stroke. Strater and colleagues¹⁴⁰ compared treatment with low-molecular-weight heparin versus aspirin in 135 children with stroke across a variety of causes (including idiopathic, cardiac, vascular, and infectious) and found no difference in efficacy or safety when used to prevent stroke recurrence. This is a controversial area, however.¹⁴¹ DeVeber¹³³ states that neonates do not require antithrombotic treatment because of negligible recurrence risk, whereas older children require aspirin (2-3 mg/kg/d).¹⁴² In dissection, high-grade stenosis, or a severe prothrombotic state, low-molecular-weight heparin or warfarin is recommended for several months. In endocarditis, anticoagulation is not recommended because of the risk of rupture of occult mycotic aneurysms. Thrombolytic therapy has been subjected to very limited study in children, although cases describing the use of tissue plasminogen activator and cerebral balloon angioplasty in acute stroke in children with dramatic results are being reported.¹⁴³ Table 60-3 compares key management issues across three sets of guidelines in acute ischemic stroke, as summarized by deVeber and Kirkham.¹⁴⁴

Since the last edition of this textbook, there has been a revolutionary change in the management of acute ischemic stroke in adults with the advent of clot retrieval. This includes numerous successful clinical trials as compared with thrombolytic therapy. Over 500 articles on this topic have been published in the past 2 years. Although these studies

are beyond the scope of this chapter, they are reviewed by Campbell et al.¹⁴⁵ To date there have been a small number of publications on clot retrieval in children. Ellis et al.¹⁴⁶ reviewed this topic and identified 34 cases of clot retrieval. More recently, Hu et al.¹⁴⁷ and Bodey et al.¹⁴⁸ presented six additional cases. Several clot retrieval systems are available including the Solitaire, Merci, and Revive. This is a promising approach, but at this juncture it can only be suggested that there may be a role for clot retrieval in children in selected patients managed by a highly experienced team.¹⁴⁸ Complications with these devices have been reported in children.¹⁴⁹ Finally, in addition to clot retrieval, as discussed in the section on stroke diagnostics, the acute management approach in pediatric stroke is also evolving rapidly on multiple fronts and additional recommendations regarding imaging and intravenous tPA treatment are available in excellent single center protocols.¹⁴⁰

Supportive Care in the Pediatric Intensive Care Unit

An evidence-based approach for care in the pediatric ICU of children with stroke is lacking. Nevertheless, intensive care for the child with stroke must be at a level commensurate with that provided for other critical pediatric neurologic disorders such as severe TBI¹⁵⁰ and ruptured arteriovenous malformation.¹⁵¹

Careful attention to the ABCs with a neurointensive care approach is essential. If the GCS score is 8 or less or the airway or ventilation is compromised, intubation is indicated and should be performed using a neuroprotective, rapid-sequence approach. Normal values for both P_{aCO_2} and P_{aO_2} should be ensured. Arterial blood pressure must be adequate to optimize cerebral perfusion. The management of systemic hypertension in the setting of pediatric stroke can be complicated by the variety of underlying disorders (e.g., status post cardiac surgery, underlying hypertension) and the presence or absence of hemorrhage. In adults with thrombotic or hemorrhagic stroke and systemic hypertension, it is generally recommended that mean arterial blood pressure not be aggressively reduced below 130 mm Hg.¹⁵² Age-appropriate guidelines for this question are not available for children.

TABLE 60-3 Comparison of Guidelines for Acute Management of Ischemic Stroke in Children by Subtype*

| | UK GUIDELINES: 2004 RECOMMENDATIONS | G | S | CHEST GUIDELINES: 2008 RECOMMENDATIONS | G | S | AMERICAN HEART ASSOCIATION: 2008 RECOMMENDATIONS | G | S |
|--------------------------------|--|-----|----|--|----|---|--|------------|--------|
| General | Aspirin 5 mg/kg | WPC | 1 | UFH or LMWH or aspirin 1-5 mg/kg/d until cardioembolic and dissection subtypes excluded | 1B | 1 | UFH or LMWH (1 mg/kg q 12 h) up to 1 week until cause determined | 2B-C | 3 |

From DeVeber G, Kirkham F. Guidelines for the treatment and prevention of stroke in children. *Lancet*. 2008;7:983-5. Reproduced with permission.

*Childhood is defined as 28 days to 18 years (*Chest*) or 1 month to 16 years (UK). Comparison of guidelines for acute management of ischemic stroke in children by subtype of stroke.

G, grade of evidence or recommendation; HbS, sickled hemoglobin; LMWH, low-molecular-weight heparin; S, strength of evidence or recommendation; UFH, unfractionated heparin; WPC, working party consensus.

In infants and children with severe stroke with infarction and cerebral swelling, signs and symptoms of raised ICP can develop. Standard protocols for monitoring ICP and treatment of raised ICP in stroke in infants and children have not been developed. Nevertheless, intracranial hypertension can develop. Should signs and symptoms of intracranial hypertension be observed, even in the absence of controlled trials in severe pediatric stroke, ICP monitoring and ICP-directed therapy should be considered. Anecdotal reports of successful treatment with a variety of therapies including mild hypothermia and decompressive craniectomy have been reported.^{153,154} Plasticity in the pediatric brain, particularly in the recovery from focal lesions, should prompt the consideration of an aggressive approach.¹⁵⁵⁻¹⁵⁷ However, long-term morbidity remains substantial after childhood stroke.¹⁵⁸

Other aspects of contemporary pediatric neurointensive care should include maintenance of euglycemia and careful fluid management both to maintain a euvoletic state and avoid hyponatremia. In children, normal saline or 5% dextrose in normal saline should be used in the initial 24 hours, carefully monitoring blood glucose concentration, followed by the addition of dextrose or initiation of hyperalimentation after 24 hours. In infants, either 5% or 10% dextrose in normal saline should be used, with insulin titrated to treat hyperglycemia. A glucose value of 200 mg/dL is a reasonable threshold in the absence of clear-cut evidence. Appropriate nutritional support should also be instituted as soon as possible. Rehabilitation services should be consulted during the pediatric ICU admission.

CRITICAL CENTRAL NERVOUS SYSTEM INFECTIONS

Any microbe may cause CNS infections; age and immune status of the host and epidemiology of the pathogen help suggest the specific pathogens. Regardless of the etiology, most children with CNS infection present with nonspecific symptoms including fever, headache, nausea, vomiting, anorexia, and irritability. Photophobia, neck pain and rigidity, seizures, mental status change, and focal neurologic deficits are common signs, depending on the specific pathogen and area of the CNS infected.

Bacterial Meningitis

Epidemiology

The etiology of bacterial meningitis and its treatment differ in neonates (0-28 days of life) versus older infants and children. During the first 2 months of life, the bacteria that cause meningitis in normal infants reflect the maternal flora and the environment to which the infant is exposed. The most common pathogens include groups B and D streptococci, gram-negative enteric bacilli, and *Listeria monocytogenes*. Occasionally, *Haemophilus influenzae* (both type B and nonencapsulated strains) and other pathogens—more typically found in older patients—can be the etiologic agent. Bacterial meningitis in children between 2 months and 12 years of age is usually caused by *Streptococcus pneumoniae*, *Neisseria meningitidis*, or *H. influenzae* type B. After the implementation of immunization against *H. influenzae*, the incidence of *H. influenzae* meningitis decreased rapidly. Subsequent to the universal recommendation for the use of conjugated pneumococcal vaccine at 2 months of age in 2000, the incidence of meningitis caused by this pathogen is also decreasing. A recent multicenter study reported Group B streptococci as the most common causative agent (86%) in children younger than 2 months, *N. meningitidis* (46%) in children 11 to 17 years, and *S. pneumoniae* in all other pediatric age groups.¹⁵⁹ Anatomic abnormalities, surgical procedures, neurotrauma, or immune deficiency often underlie meningitis caused by other agents.

Bacterial meningitis most commonly results from hematogenous dissemination of microorganisms from a distant site of infection. Colonization of the nasopharynx with a pathogenic microorganism is the usual source of bacteremia. Bacteria gain entry to the CSF through the choroid plexus of the lateral ventricles and the meninges and then circulate to the extracerebral CSF and the subarachnoid space.

Bacterial cell wall lipopolysaccharides of gram-negative bacteria and pneumococcal cell wall components stimulate a marked inflammatory response, with local production of tumor necrosis factor alpha, interleukin-1 β , prostaglandin E, and other mediators, leading to neutrophil infiltration, increased vascular permeability, and thrombosis. Inflammation of spinal nerves and roots produces meningeal signs, and inflammation of the cranial nerves produces optic, oculomotor, facial, and auditory neuropathies. Intracranial hypertension can produce oculomotor and abducens nerve palsy. Intracranial hypertension in meningitis is believed to result from a combination of cell death (cytotoxic cerebral edema), cytokine-induced increased capillary vascular permeability (vasogenic edema), and increased hydrostatic pressure after obstruction of CSF reabsorption or flow. Rarely, meningitis may follow bacterial invasion from a contiguous focus of infection such as paranasal sinusitis, otitis media, mastoiditis, orbital cellulitis, or cranial or vertebral osteomyelitis or may occur after introduction of bacteria via penetrating head trauma or meningomyelocele.¹⁶⁰

Diagnosis

The clinical presentation may be as fulminant as rapidly progressing shock, purpura, disseminated intravascular coagulation, and altered consciousness, frequently resulting in death within 24 hours. More often, however, children present with several days of fever with upper respiratory tract or gastrointestinal symptoms, followed by nonspecific signs of CNS infection such as lethargy and irritability. The presence of headache, emesis, bulging fontanelle, widening of the sutures, oculomotor or abducens nerve paralysis, hypertension with bradycardia, apnea, or hyperventilation suggests intracranial hypertension. Papilledema is uncommon in uncomplicated meningitis and suggests a more chronic process, such as intracranial abscess, sinus thrombosis, or subdural empyema. Seizures can result from cerebritis, infarction, or electrolyte abnormalities and occur in between 20% and 30% of cases. Seizures that occur at presentation or within the first 4 days of onset are usually of no prognostic significance. Seizures that persist beyond day 4 and those that are difficult to treat are associated with a poor prognosis.¹⁶¹

The diagnosis of acute bacterial meningitis is confirmed by analysis of CSF. Contraindications for an immediate lumbar puncture are (1) evidence of increased ICP (other than a bulging fontanelle), (2) presence of severe cardiopulmonary compromise or likelihood that positioning for the procedure would significantly compromise cardiopulmonary function, (3) infection of the skin overlying the needle insertion site, and (4) coagulopathy. If lumbar puncture is delayed, empirical antibiotic treatment should be started after a blood culture is obtained. Blood culture reveals the causative bacteria in 80% to 90% of cases of meningitis. The need for a cranial CT scan for signs and symptoms of increased ICP or brain abscess should not delay therapy. Table 60-4 summarizes the CSF findings in CNS infections. Pleocytosis with lymphocyte predominance may be seen early in bacterial meningitis; conversely, neutrophilic pleocytosis may be present in patients during the early stages of acute viral meningitis. The shift to lymphocytic-monocytic predominance in viral meningitis invariably occurs within 8 to 24 hours. A traumatic lumbar puncture complicates the diagnosis. If the CSF is bloody, it should be collected in three or more tubes. If it clears in successive tubes, it suggests a traumatic puncture. Blood that does not clear is more suggestive of intracranial bleeding. The CSF leukocyte-to-erythrocyte ratio in CSF from a traumatic lumbar puncture is generally similar to that in a concurrently obtained peripheral blood sample (usually 1:500 to 1:1000).¹⁶²

The mortality rate of bacterial meningitis after the neonatal period is less than 10%. Severe neurodevelopmental sequelae occur in between 10% and 20% of pediatric patients. The most common sequelae include hearing loss, mental retardation, epilepsy, delay in language acquisition, visual impairment, and behavioral problems. Sensorineural hearing loss occurs in 30%, 10%, and 5% to 10% of patients with pneumococcal, meningococcal, and *H. influenzae* type B meningitis, respectively.¹⁶³

TABLE 60-4 Cerebrospinal Fluid Findings in Central Nervous System Infections

| TYPE OF INFECTION | PRESSURE (cm H ₂ O) | LEUKOCYTES (mm ³) | PROTEIN (mg/dL) | GLUCOSE (mg/dL) |
|---|--------------------------------|--|---------------------------------|--|
| Normal | 5-8 | <5, ≥75% lymphocytes <30 for neonates | 20-45 Up to 180 for neonates | >50 (or 75% serum glucose) |
| Acute bacterial | ↑ (10-30) | 300-2000 PMNs predominate | 100-500 | ↓ (<40 or <50% serum glucose) |
| Partially treated bacterial meningitis | Normal or ↑ | 5-10,000 Usually PMNs | 100-500 | Normal or ↓ |
| Viral meningitis or meningoencephalitis | Normal or slightly ↑ (8-15) | Rarely >1000 PMNs early, then mononuclear cells | 50-200 | Normal (decreased in some mumps cases) |
| Tuberculous meningitis | ↑ | 10-500 PMNs early, lymphocytes predominate through most of the course | 100-3000 | <50 |
| Fungal meningitis | ↑ | 5-500 PMNs early, lymphocytes predominate through most of the course | 25-500 | <50 |
| Syphilis | ↑ | 50-500 Lymphocytes predominate | 50-200 | Normal |
| Amebic (<i>Naegleria</i>) meningoencephalitis | ↑ | 1000-10,000 or more PMNs predominate | 50-500 | Normal or slightly ↓ |

PMNs, polymorphonuclear leukocytes.

Treatment

The initial empirical choice of antibiotic treatment in immunocompetent infants and children is primarily determined by the antibiotic susceptibilities of *S. pneumoniae*. In the United States, between 25% and 50% of strains of *S. pneumoniae* are currently resistant to penicillin, and up to 25% of isolates are resistant to cefotaxime or ceftriaxone. Thus, empirical therapy is with vancomycin (60 mg/kg/24 h, divided, every 6 h) and cefotaxime (200 mg/kg/24 h, divided, every 6 h) or ceftriaxone (100 mg/kg/24 h, given either as a single daily dose or every 12 h). Patients allergic to beta-lactam antibiotics can be treated with chloramphenicol (100 mg/kg/24 h, divided, every 6 h). If *L. monocytogenes* infection is suspected, as in infants between 1 and 2 months of age or patients with T-lymphocyte deficiency, ampicillin (200 mg/kg/24 h, divided, every 6 h) should be administered with either cefotaxime or ceftriaxone. In addition, empirical acyclovir therapy for herpes simplex virus should be considered, especially in febrile neonates with rash, seizure, maternal history, or ill appearance, since delayed therapy of neonatal herpes simplex virus disease has been associated with increased mortality. If a patient is immunocompromised and gram-negative bacterial meningitis is suspected, ceftazidime and an aminoglycoside may be used as initial therapy. The duration of treatment should be either 10 or 14 days, depending on the bacteria; gram-negative bacillary meningitis should be treated for 3 weeks or for at least 2 weeks after sterilization of CSF. Repeat lumbar puncture may be indicated in some neonates and in children with gram-negative meningitis or infection caused by beta-lactam-resistant *S. pneumoniae*. Of the adjunctive treatments that might limit CNS inflammation, only corticosteroids have been properly assessed in clinical trials. Adjuvant corticosteroid use was associated with lower case fatality and lower rates of both severe hearing loss and long-term neurologic sequelae in acute bacterial meningitis. Corticosteroids administered either before or with the first dose of antibiotic reduced severe hearing loss in bacterial meningitis caused by *H. influenzae* as well as in meningitis caused by *S. pneumoniae*.¹⁶⁴ The recommended dose of dexamethasone is 0.6 mg/kg/24 h, divided every 6 hours for 4 days.¹⁶⁰ A recent meta-analysis of individual patient data from 25 randomized, placebo-controlled trials in both adults and children addressing corticosteroid use in meningitis showed that corticosteroid administration decreased the rate of hearing loss in children with meningitis due to *H. influenzae* (4% versus 12%) but not in children with meningitis due to other bacteria. Dexamethasone did not

significantly reduce the death rate.¹⁶⁴ Two randomized controlled trials (RCT) of dexamethasone alongside standard antibiotic therapy in neonatal bacterial meningitis suggest some reduction in death and hearing loss; however, they were deemed to contain very low-quality data in a recent systematic review. There are no data about the role of corticosteroids in patients with nosocomial or CSF shunt-associated meningitis. Thus, the role of dexamethasone in prevention of death or neurologic sequelae needs reevaluation.

Peltola et al.¹⁶⁵ reported improved outcomes in 654 children with meningitis with oral glycerol therapy (6 mL/kg/d divided in 4 doses; maximum 25 mL/dose). However, another study did not demonstrate benefit from oral glycerol on hearing impairment in pediatric meningitis.¹⁶⁶ Nevertheless, glycerol has been recommended for pediatric meningitis, albeit not at a guidelines level.¹⁶⁷ Recent reviews, however, state that osmotic diuretics, including glycerol, should be given to children with bacterial meningitis only as part of RCTs. A recent RCT that compared CPP- vs. ICP-targeted therapy in acute bacterial meningitis in children warrants mentioning in this update of the chapter.¹⁶⁸ In this study 110 comatose children (aged 1-12 yr) with acute CNS infection undergoing invasive ICP monitoring were randomized to a target level of ICP (<20 mm Hg) or to target level of CPP (>60 mm Hg). CPP-targeted therapy necessitated frequent use of vasopressors and less use of hyperventilation and osmotherapy. It was superior to ICP-targeted therapy in reducing mortality and morbidity.

Patients who (1) manifest poor perfusion, cutaneous signs of disseminated intravascular coagulation (purpura, petechiae), irregular respiratory pattern, altered mental status, cranial nerve involvement, and other signs potentially indicative of raised ICP and patients who (2) have a rapid clinical presentation, significant metabolic acidosis, hypoxemia, hypercapnia, neutropenia, hyponatremia, anemia, or abnormal liver or renal function should be admitted to the pediatric ICU. At least until the course of illness can be determined, the first several doses of antibiotics are administered and a tentative bacteriologic diagnosis is made. Early recognition of complications such as shock or raised ICP and initiation of treatment in a timely fashion may improve the outcome in fulminant meningitis.

Acute CNS complications during the treatment of meningitis include seizures, intracranial hypertension, cranial nerve palsies, stroke, herniation, and thrombosis of the dural venous sinuses.¹⁶⁹ Subdural effusions develop in between 10% and 30% of pediatric patients

and are more common in infants. They are asymptomatic in 85% to 90% of cases. Aspiration of subdural effusions is indicated in the presence of raised ICP; fever alone is not an indication for aspiration. The syndrome of inappropriate secretion of antidiuretic hormone (SIADH) with hyponatremia and reduced serum osmolality occurs in between 30% and 50% of children. Cerebral salt wasting can also be seen. Attention to maintaining a normal serum sodium concentration using either normal saline or judicious titration of hypertonic saline is important for preventing exacerbation of brain edema. Prolonged fever (>10 days) occurs in 10% of patients. It is usually due to intercurrent viral infection, secondary or nosocomial bacterial infection, thrombophlebitis, drug reaction, pericarditis, or arthritis.

Supportive Care in the Pediatric ICU

The issues in ICU care for infants and children with bacterial meningitis are similar to ones mentioned under encephalitis. The reader is referred to the following section for details.

Viral Encephalitis

Epidemiology

Enteroviruses are the most common etiologic agent of encephalitis in children. Severity ranges from mild illness to severe encephalitis with death or long-term morbidity. Enterovirus infections spread directly from person to person, with an incubation period of between 4 and 6 days. Most cases occur in summer and fall in temperate climates. Arboviruses are responsible for some cases of encephalitis. The most common arboviruses causing CNS infection in the United States are St. Louis and California encephalitis and West Nile virus.¹⁷⁰

Several members of the herpesvirus family can cause encephalitis. Herpes simplex virus (HSV) type 1 is an important cause of severe encephalitis in children. The cerebral cortex, especially the temporal lobe, is often severely affected by HSV. Neonatal herpes infections are usually caused by HSV type 2 contracted at delivery via vertical transmission. Three forms of the disease develop in neonates: (1) skin, eye, mouth disease (45% of cases), (2) encephalitis (35%), and (3) disseminated intravascular coagulation (20%). The transmission rate from mother to infant is between 30% and 40% with a primary genital infection and 3% for reactivated herpes infection. The mean age at onset of cutaneous or systemic disease is 6 days after birth, with the mean onset of encephalitis at 11 days. The diagnosis of HSV infection in neonates can be difficult to make unless skin lesions are present. Cultures of conjunctiva, nasopharynx, and rectum between 48 hours and 72 hours of age may identify early infection. In neonates, the mortality rates are about 50% and 14% for HSV-disseminated disease and encephalitis, respectively.¹⁷⁰

A number of other viruses are important causes of pediatric encephalitis. Varicella-zoster may cause CNS infection in close proximity to chickenpox. The most common manifestation of CNS infection by varicella-zoster is cerebellar ataxia. Cytomegalovirus infection of the CNS may be either part of congenital infection or disseminated disease in an immunocompromised host. CNS diseases caused by Epstein-Barr virus may present with perceptual distortions of sizes, shapes, and spatial relationships known as "Alice in Wonderland syndrome." There may be meningitis, seizures, ataxia, facial palsy, transverse myelitis, and encephalitis.¹⁷⁰ During the influenza A (H1N1) pandemic, neurologic sequelae were significant. As reported by Baltagi et al.,¹⁷¹ these findings in children included altered mental status, seizures, and encephalopathy, even without significant respiratory symptoms.

Infectious agents can enter the brain via a hematogenous route or by neuronal tracts. Many hematogenous pathogens cause direct endothelial damage to arteries, arterioles, and capillaries, resulting in vasculitis, hemorrhage, and thrombosis. Postinfectious encephalitis is an autoimmune process characterized by a perivenulitis with demyelination. It is uncommon in children younger than 1 year of age.¹⁷² The mortality rate of herpes infection even with early acyclovir treatment is 20% to 30%, and there is substantial morbidity.¹⁷³

Diagnosis

The onset of illness is generally acute and often preceded by a nonspecific febrile illness of a few days' duration. The manifestations of viral encephalitis in older children are headache and hyperesthesia, whereas in infants, irritability and lethargy predominate. Adolescents frequently complain of retrobulbar pain, fever, nausea, vomiting, photophobia, and pain in the legs, back, and neck. Exanthems often precede or accompany the CNS signs. Seizures occur in 60% of cases of HSV encephalitis. The CSF usually shows a mild mononuclear predominance. It should be cultured for viruses, bacteria, fungi, and mycobacteria. Detection of viral DNA or RNA by polymerase chain reaction is useful for diagnosis of HSV, varicella-zoster, cytomegalovirus, Epstein-Barr virus, and enteroviral meningoencephalitis. Polymerase chain reaction in CSF is 100% specific and more than 90% sensitive for HSV.¹⁷⁴ About 50% of patients with HSV encephalitis have focal abnormalities on nonenhanced CT. MRI is the imaging modality of choice and should ideally be the first step after the clinical exam. The EEG is abnormal in almost all cases of HSV encephalitis and may show periodic lateralized epileptiform discharges.¹⁷⁵

Immune-mediated encephalitis, most commonly acute disseminated encephalomyelitis, can be triggered by viral encephalitis. Recurrences of neurologic symptoms after HSV encephalitis can be due to recurrence of HSV or the appearance of autoantibodies. Immune-mediated encephalitis is diagnosed by detecting antibodies directed against specific cell-surface proteins.¹⁷⁶ In some cases the diagnostic work up should include (1) anti-NMDA receptor antibodies, usually immunoglobulin IgG, in serum or CSF (for NMDA-receptor encephalitis); (2) antithyroid peroxidase IgG in serum or occasionally CSF (for steroid-responsive encephalopathy associated with autoimmune thyroiditis); and (3) leucine-rich glioma-inactivated protein 1 IgG in serum, voltage-gated potassium channel complex antibodies in serum, anti-glutamic acid decarboxylase IgG in CSF, and anti-GABA_B receptor IgG in serum (for limbic encephalitis). Diagnosis of immune-mediated encephalitis is important since it changes therapy. Apart from requiring additional laboratory tests, immune-mediated encephalitis can also manifest with different or additional symptoms compared with viral encephalitis, such as movement disorders, cataplexy, hallucinations, and paranoia in NMDA-receptor encephalitis; coreas, tics, and focal neurologic deficits in autoimmune thyroiditis-associated encephalopathy; and memory dysfunction in limbic encephalitis. Although rare in children, teratomas, most commonly in the ovary, can trigger anti-NMDA receptor encephalitis; thus MRI of the pelvis and abdomen should be considered in girls with this disorder.

Treatment

Antiviral therapy with acyclovir is indicated for HSV encephalitis. Acyclovir has a relatively short half-life in plasma, and more than 80% is excreted unchanged in the urine, so renal impairment can exacerbate toxicity. The standard dose of acyclovir for HSV encephalitis is 30 mg/kg/24 h, divided every 8 hours for 14 days. The dose in neonates is 60 mg/kg/d. The duration of treatment is 21 days for immunocompromised patients. Acyclovir is effective in encephalitis due to HSV types 1 and 2 and varicella-zoster. The dose of acyclovir for varicella-zoster encephalitis is similar to that for HSV.¹⁷⁴ Antiviral therapy with oseltamivir is indicated in H1N1 encephalopathy.¹⁷¹ Immunotherapy (most commonly methylprednisolone, IV immunoglobulin and plasmapheresis, or rituximab and cyclophosphamide in patients refractory to first-line therapy) has a major role in the treatment of immune-mediated encephalitis. Immunotherapy also has a role in the management of children or adolescents with recurrence of neurologic symptoms after recovery from HSV encephalitis.¹⁷⁶

Supportive Care in the Pediatric Intensive Care Unit

Data supporting an evidence-based approach to pediatric ICU care of children with meningitis and encephalitis is lacking. Careful attention to the ABCs with a neurointensive care approach is essential. If the GCS score is less than 8 or the airway or ventilation is compromised,

intubation should be performed using a neuroprotective rapid-sequence approach. Normal values for both PaCO_2 and PaO_2 should be ensured. Bacterial meningitis and encephalitis can be associated with severe septic shock that should be treated according to published guidelines.¹⁷⁷ Arterial blood pressure must be adequate to optimize cerebral perfusion.

In infants and children with meningitis and encephalitis, increased ICP may develop. The most important cause of morbidity and mortality in CNS infections is herniation of brain tissue secondary to intracranial hypertension. While the study of Kumar et al. described above suggested that CPP-targeted therapy might be superior to ICP-targeted therapy,¹⁶⁸ available evidence supports the association of intracranial hypertension with poor neurologic outcome in infants and children.¹⁷⁸⁻¹⁸⁰ In addition, ICP monitoring and aggressive treatment of intracranial hypertension showed reduction in the expected mortality rate in pediatric and adult patients with meningitis and encephalitis.¹⁸¹⁻¹⁸⁴ ICP monitoring and ICP-directed therapy should be considered if signs and symptoms of intracranial hypertension develop. ICP monitoring in patients with known or suspected CNS infection with a GCS score less than 8 may be considered at the discretion of the physician. An external ventricular drain is the preferred method of ICP monitoring if there is hydrocephalus or therapeutic CSF drainage is required.

Other aspects of contemporary pediatric neurointensive care should be addressed as noted above, including maintenance of euglycemia and euolemia and avoidance of hyponatremia. This is important because SIADH is common. Nutritional support as outlined in Chapter 44 should also be instituted as soon as possible.

Brain Abscess

Epidemiology and Diagnosis

Brain abscesses are most common in children between the ages of 4 and 8 years. The underlying causes of brain abscess include chronic otitis media and sinusitis, orbital cellulitis, dental infections, penetrating head injury, infection of ventriculoperitoneal shunts, immunodeficiency states, embolization due to congenital heart disease with left-to-right shunts, and meningitis. About 80% of brain abscesses in children occur in the frontotemporal and parietal lobes, and 30% involve multiple sites. Table 60-5 summarizes the relationships between predisposing conditions and site of brain abscess, likely pathogens, and suggested initial empirical treatment. In the early stages, the clinical presentation of brain abscess includes low-grade fever, headache, and lethargy. Vomiting, papilledema, focal neurologic signs, and seizures may develop as the inflammation proceeds. Nystagmus, ipsilateral ataxia and dysmetria, headache, and vomiting are characteristic signs of cerebellar brain abscess. If the abscess ruptures into the ventricular cavity, severe shock may develop rapidly, and death may result.¹⁸⁵

Contrast-enhanced head CT and MRI are the most reliable methods of identifying brain abscess. An abscess cavity shows a ring-enhancing

lesion with enhanced CT. MRI with gadolinium administration may reveal a capsule. Blood cultures are positive in about 10% of cases. Lumbar puncture should not be undertaken in a patient with suspected brain abscess. Examination of CSF is seldom useful, and this procedure may precipitate herniation.

Treatment

Treatment is initiated with an antibiotics based on the probable pathogenesis and most likely organism. An encapsulated abscess should be treated with antibiotics and aspiration, which is also the best diagnostic approach. Surgery is indicated when the abscess (1) is larger than 2.5 cm in diameter, (2) contains gas, (3) is multiloculated, (4) is located in the posterior fossa, or (5) when fungus is identified. The duration of treatment depends on the organism and response but usually ranges between 4 and 6 weeks. Other aspects of neurointensive care in the pediatric ICU for infants and children with brain abscess should mirror those presented for meningitis and encephalitis.¹⁸⁶

POSTOPERATIVE NEUROSURGICAL CASES

Epidemiology

Neurosurgical procedures for children vary widely and include elective and emergent operations at all ages for a variety of illnesses, most commonly brain tumors, hydrocephalus, and arteriovenous malformations.

Diagnosis

The need for admission to a pediatric ICU is largely determined by the potential complications associated with the surgery involved. The most common complications that require intensive monitoring include hydrocephalus, airway compromise, bleeding, vascular complications, fluid and electrolyte abnormalities, and seizures. Persistent hydrocephalus is an obvious concern in patients treated for this problem, either with shunting, ventriculostomy, or a decompressive procedure. Patients with congenital hydrocephalus require ICU monitoring as determined largely by their preoperative status. A child with slowly progressive hydrocephalus with few clinical symptoms may not require ICU admission, whereas preoperative symptoms that raise a concern of potential herniation will require close observation and monitoring. Patients with Chiari malformations, tumors impinging on CSF drainage, or ventricular hemorrhages all carry a significant risk of developing postoperative hydrocephalus.

Airway compromise is a potentially life-threatening complication that is of particular concern after neurosurgical procedures involving the brainstem, because vocal cord paralysis or cranial nerve damage is possible. Patients with congenital facial abnormalities are also at risk for respiratory compromise. A third scenario that predisposes neurosurgical patients to airway problems is a procedure requiring

TABLE 60-5 Predisposing Conditions, Etiologic Agents, and Empirical Treatment in Brain Abscess

| PREDISPOSING CONDITION | SITE OF ABSCESS | ETIOLOGIC AGENTS | TREATMENT |
|---|-------------------------------------|--|---|
| Sinusitis Orbital cellulitis Dental infection | Frontal lobe | Streptococci, <i>Bacteroides</i> , Enterobacteriaceae, <i>Staphylococcus aureus</i> , <i>Haemophilus</i> spp. | Vancomycin + third-generation cephalosporin + metronidazole |
| Otitis media Mastoiditis | Temporal lobe/cerebellum | Streptococci, <i>Bacteroides</i> , Enterobacteriaceae, <i>S. aureus</i> , <i>Haemophilus</i> spp., <i>Pseudomonas aeruginosa</i> | Vancomycin + third-generation cephalosporin + metronidazole |
| Head trauma Postsurgical infection | Site of injury or surgery | <i>S. aureus</i> , streptococci, Enterobacteriaceae, <i>Clostridium</i> | Vancomycin + third-generation cephalosporin + metronidazole |
| Congenital cyanotic heart disease | Middle cerebral artery distribution | <i>Streptococcus viridans</i> , anaerobic and microaerophilic streptococci | Penicillin + metronidazole |
| Ventriculoperitoneal shunt | Site of shunt | <i>P. aeruginosa</i> , streptococci, Enterobacteriaceae | Vancomycin + ceftazidime |

prone positioning during surgery, because significant facial swelling can result.

Although the potential for bleeding is always a concern after surgical procedures, several diseases carry more than the typical risk for hemorrhage. Surgical resection of a vascular malformation is of concern for bleeding if resection is incomplete. However, all procedures carry some risk for postoperative bleeding, including procedures that do not involve a craniotomy. Surgical procedures near major arteries can cause vasospasm with resultant cerebral ischemia or infarct. Subarachnoid hemorrhage from aneurysmal or vascular malformation rupture is another well-known cause of vasospasm.

Electrolyte abnormalities can result from three disturbances in normal regulatory mechanisms: diabetes insipidus, SIADH, and cerebral salt wasting (see later discussion for management). Other complications from neurosurgical procedures include CSF leak, aseptic meningitis, and pseudomeningocele.

Physical Examination

The immediate examination should include an evaluation of the ABCs. Specific to neurosurgical patients, however, a rapid neurologic examination is important to evaluate for baseline deficits after surgery. This is essential for evaluation of subsequent changes in neurologic status. For example, unequal pupillary size may be a result of surgical intervention and would be present immediately after the surgery. However, development of unequal pupils in a patient who previously had equal pupillary size may be the first sign of impending herniation. The initial neurologic examination should include a gross evaluation of mental status. Patients routinely have a depressed level of consciousness after anesthesia, but repeated examinations are necessary to ensure that mental status continues to improve. Measurement of the GCS score is one means of objectively quantifying a child's level of consciousness. Cranial nerve examination is limited by the child's ability to cooperate but should include pupillary response (cranial nerve II), observation of extraocular movements (cranial nerves III, IV, and VI), jaw deviation during sucking in an infant (cranial nerve V), facial asymmetry while crying or laughing (cranial nerve VII), gag reflex (cranial nerves IX and X), and shoulder droop (cranial nerve XI). The motor exam relies on careful observation of movements, because few patients will be able to cooperate with a formal exam early after surgery. The sensory examination involves observing gross responses to stimuli. A full evaluation of deep tendon reflexes is usually possible. Neurologic evaluation should be repeated frequently during the first 24 hours, evaluating for new or progressing deficits.

Treatment

All patients in the pediatric ICU should have cardiorespiratory monitoring. Respiratory monitoring should be designed to warn of impending airway compromise, including measurement of respiratory rate, pulse oximetry, and repeated examinations evaluating work of breathing, air entry, and evidence of stridor. Hemodynamic monitoring is useful for evaluating both hemodynamic and neurologic status. Increases in heart rate and BP can be an indication of pain or of seizure activity. Increased BP with a low heart rate is worrisome as it suggests raised ICP and impending herniation, although herniation is not always signaled by Cushing's triad in children. Tachycardia with prolonged capillary refill or hypotension may indicate excessive fluid losses, either from bleeding, third space losses, or excessive urine output. Tachycardia and hypotension can also result from loss of vasomotor tone, from infection, medications, or loss of neurologic regulation after spinal surgery. Invasive BP monitoring is necessary when patients are at high risk for any of the complications listed earlier. Strict measurement of fluid intake and output is essential to monitor fluid balance and interpret disturbances in fluid and electrolyte regulation. When the surgical procedure carries a high risk of inducing fluid regulation abnormalities, as in craniopharyngioma resections, serum and urine electrolytes should be tested every 4 to 6 hours, along

with continuous monitoring of urine output and central venous pressure. Temperature control is important and should therefore be monitored closely. Aggressive measures to prevent hyperthermia are warranted because neurologic injury may be exacerbated by high brain temperature.

Fluid management for the postoperative neurosurgical patient differs from that for other postoperative patients. Although maintenance of circulating volume is important, it is critical to avoid excessive hydration to limit cerebral edema. In general, neurosurgical procedures do not result in the large third-space losses seen with other surgeries. Once adequate volume status is achieved to maintain perfusion, fluid requirements will usually be met with a maintenance fluid rate.

Euglycemia is important after neurologic surgery, because both hypo- and hyperglycemia can exacerbate neurologic injury. Based on recommendations in adults, initial IV fluids in older children should generally be normal saline or 5% dextrose in normal saline, and serum glucose levels should be monitored closely. The duration for dextrose restriction in older children is controversial because ketosis develops even with euglycemia. Generally this is maintained for the initial 24 hours. Hyperglycemia, however, should probably be avoided throughout the entire acute period after CNS insults. Infants, on the other hand, do not have the same capacity for maintaining serum glucose levels if given no source of carbohydrate intake. Initial dextrose concentration in fluid for the infant with a CNS insult should probably be 5% (in normal saline). When higher dextrose concentrations are used, such as with hyperalimentation, hyperglycemia should be carefully managed with insulin infusion. The risk of exacerbation of brain injury by hyperglycemia in infants and children is likely but somewhat theoretical. In contrast, it is clear that hypoglycemia can be harmful to the injured brain and should be avoided.

Hyponatremia is of particular concern in neurosurgical patients, because the osmotic effects can result in increasing cerebral edema. The incidence of hyponatremia has been reported to be as high as 31% at 48 hours in pediatric surgical patients.¹⁸⁷ The use of isotonic fluids in the pediatric ICU can reduce the incidence of iatrogenic hyponatremia.¹⁸⁸ Thus, normal saline is the preferred IV fluid to avoid this complication. When hyponatremia occurs in conjunction with a decreasing urine output, a high specific gravity, and a high sodium concentration in the urine, it is likely the result of SIADH. In this case, fluid restriction is indicated. Neurosurgical patients also have two unique possible sources for excessive sodium loss: CSF loss from extraventricular drainage and urine loss from cerebral salt wasting. Both require correction of sodium loss.

Mild hypernatremia is generally not detrimental and is usually a result of excessive sodium intake or osmotic diuresis. A progressively increasing serum sodium concentration in the presence of an increasing volume of hypo-osmolar urine, however, suggests diabetes insipidus. This complication is unusual except with surgeries that have the potential for pituitary injury. Management of diabetes insipidus requires careful titration of fluids, with a maintenance rate to cover insensible losses (300 mL/m²/d) plus total replacement of urine output with a fluid that matches the urine electrolyte concentrations. Vasopressin or desmopressin therapy may be required to control the free water loss.

A few medications should be considered for every neurosurgical patient. First, antiemetics are important to prevent postanesthesia nausea and vomiting, because vomiting can cause a dramatic increase in intracranial pressure. Ondansetron and droperidol are good choices for antiemetic therapy because they are minimally sedating.¹⁸⁹ Postoperative seizures can have serious consequences, so antiepileptics should be considered in all patients deemed to be at risk. Typically, phenytoin is the least sedating drug for seizure prophylaxis. Patients on chronic anticonvulsants should have their usual regimen restarted as soon as possible after the surgery. Dexamethasone is used to reduce edema around brain tumors and reduce tumor size.¹⁹⁰ The use of corticosteroids is controversial in most other settings. However, patients who received corticosteroids preoperatively may require stress-dose corticosteroids during the postoperative period. Prophylaxis with H₂ blockers

may reduce gastrointestinal hemorrhage in critically ill patients¹⁹¹ but may also increase the risk of nosocomial infections.¹⁹² Gastrointestinal bleeding is more common after resection of a posterior fossa tumor, and use of prophylaxis has been advocated in these patients.¹⁹³

Emergency Intervention

The postoperative problem of most concern, and sometimes the most difficult to evaluate in a child, is an altered mental status. Although anesthetics or narcotics can produce an altered sensorium, emergent evaluation is indicated if reversal of these medications does not yield a reassuring examination. If the patient's GCS score is less than 8, intubation should be performed before any transport or testing. If an extraventricular drain is in place, it should be open and low enough to allow CSF drainage. Mannitol or hypertonic saline should be given if signs of impending herniation exist and transient hyperventilation begun until a definitive surgical intervention is carried out. An emer-

gent head CT should then be performed. Further action will be guided by the CT findings.

OTHER CRITICAL CENTRAL NERVOUS SYSTEM DISORDERS IN INFANTS AND CHILDREN

There are other critical CNS disorders in infants and children, including hepatic encephalopathy, hypertensive encephalopathy, and Reye syndrome. Discussion of these and other less common disorders is beyond the scope of this chapter, and the reader is referred to the appropriate primary references or other textbooks focused on pediatric critical care medicine. Reye syndrome was once a key disorder in the field of pediatric neurointensive care, reaching a peak of 555 cases in the United States in 1980. In the past decade, fewer than 2 cases per year have been reported.¹⁹⁴

KEY POINTS

1. There are important age-related differences in both CNS insults and the response to these insults in infants and children.
2. Neurointensive care for infants and children should focus on preventing secondary extracerebral insults and optimizing brain-directed therapies. Optimization of cardiopulmonary physiology, maintenance of euglycemia, and prevention of hyperthermia and hyponatremia are important for best outcomes. Pediatric neurocritical care services can help standardize and optimize care.
3. Cardiopulmonary arrest in infants and children results from asphyxia in the majority of cases.
4. The goals of treating status epilepticus are to provide respiratory and cardiovascular support, terminate seizure activity, identify and treat the precipitating factors, and prevent systemic complications. Continuous EEG monitoring is gaining acceptance.
5. Congenital and acquired heart diseases are the most important underlying causes of embolic stroke in infants and children. Clot retrieval is revolutionizing adult stroke care but is still exploratory in pediatric neurocritical care.
6. The etiology and treatment of bacterial meningitis differ between neonates and older infants and children.
7. Herpes simplex virus is an important cause of severe encephalitis in children.
8. Treatment of impending herniation includes immediate airway control, mannitol or hypertonic saline administration, hyperventilation, cerebrospinal fluid drainage (if available), and emergent CT evaluation.

Important multicenter randomized controlled trial showing beneficial effect of mild hypothermia in perinatal asphyxia.
- Topjian AA, Berg RA, Nadkarni VM. Pediatric cardiopulmonary resuscitation: advances in science, techniques, and outcomes. *Pediatrics* 2008;122:1086-1098.
Comprehensive review of the pathobiology and treatment of pediatric cardiac arrest.
- Vavilala MS, Lee LA, Lam AM. The lower limit of autoregulation in children during sevoflurane anesthesia. *J Neurosurg Anesthesiol* 2003;15:307-312.
Important study that shows that the lower limit of CBF autoregulation in infants and young children is similar to that in older children—indicating enhanced vulnerability of the brain of infants and young children to hypotension, given the reduced autoregulatory reserve (difference between mean arterial pressure and the lower limit of autoregulation).

The clinical management of patients with acute respiratory failure is based on the assumption that significant abnormalities in respiratory mechanics, respiratory muscle performance, and control of breathing are the underlying mechanisms responsible for acute respiratory failure.¹ The effects of mechanical ventilation on gas exchange, respiratory muscle load, and dyspnea depend on the matching between the ventilator settings and the patient's respiratory physiology. However, mechanical ventilation is rarely optimized, which would require ventilator settings based on accurate and reproducible measurements of lung and chest wall mechanics, respiratory muscle function, and respiratory drive.²⁻⁵

■ RESPIRATORY PHYSIOLOGY

The goal of the intrinsic ventilatory control system is to integrate the timing and intensity of the phrenic nerve signal, inputs from chemoreceptors and pulmonary stretch receptors, and variations in metabolic demands. Contraction of the respiratory muscles leads to the generation of flow and volume to provide adequate alveolar ventilation with minimal work of breathing.⁶ During spontaneous breathing,⁷ the respiratory muscles generate pressure (P_{mus}) to produce flow against the resistive properties (R_{RS}) and volume against the elastic properties (E_{RS}) of the respiratory system and to eventually overcome intrinsic positive end expiratory pressure (PEEPi). Under these circumstances, the act of spontaneous breathing can be described at any instant as follows:

$$P_{\text{mus}} = P_{\text{res}} + P_{\text{el}} + \text{PEEPi} \quad (\text{Equation 1})$$

where P_{res} represents the resistive pressure and is a function of flow ($P_{\text{res}} = \text{Flow} \times R_{\text{RS}}$), and P_{el} represents the elastic recoil pressure and is a function of volume ($P_{\text{el}} = \text{Volume} \times E_{\text{RS}}$). Assuming that R_{RS} and E_{RS} are linear, the equation becomes:

$$P_{\text{mus}} = (\text{Flow} \times R_{\text{RS}}) + (\text{Volume} \times E_{\text{RS}}) + \text{PEEPi} \quad (\text{Equation 2})$$

In patients with acute respiratory failure requiring ventilatory support, pressure generated by the ventilator (P_{appl}) is added to the pressure generated by the contraction of the respiratory muscles according to the following equation:

$$P_{\text{mus}} + P_{\text{appl}} = (\text{Flow} \times R_{\text{RS}}) + (\text{Volume} \times E_{\text{RS}}) + \text{PEEPi} \quad (\text{Equation 3})$$

The complex interaction among all the variables in Equation 3 can be summarized by the concept of neuroventilatory coupling (Fig. 61-1).⁸ Under normal conditions, as well as at the onset of acute respiratory failure, the spontaneous contraction of the respiratory muscles suddenly generates flow and volume; the slope of the relationship between effort and ventilatory output is conditioned by the contractile properties of the respiratory muscles and the impedance of the respiratory system. When positive pressure is applied to assist the action of breathing in most common modes of mechanical ventilation, the coupling between the effort and output may be compromised.

During volume-targeted assist-control ventilation (ACV), flow and volume remain constant despite changes in muscle contraction. During pressure-targeted flow-cycled (pressure support ventilation [PSV]) or time-cycled (assist-control pressure-targeted ventilation [AC/PCV]) ventilation, despite better coupling between inspiratory effort and ventilatory output, any increase in respiratory impedance decreases the amount of delivered flow and volume.⁸ During noninvasive ventilation (NIV), air leaks may further compromise the coupling between the patient effort and ventilatory output.⁹

■ PATIENT AND VENTILATOR VARIABLES

Patient Variables

The patient interacts with the ventilator based on three physiologic variables^{2,10,11}:

1. Respiratory drive¹²
2. Ventilatory requirements⁵
3. Timing of the breathing pattern¹⁰

Ventilator Variables

The ventilator interfaces with the patient's physiology based on three technologic variables:

1. The delivery mechanisms (control variable); that is, the algorithm used by the ventilator to assist ventilation through the delivery of flow, volume, or pressure¹³⁻¹⁸
2. The inspiratory trigger (phase trigger variable), or when the ventilator starts to deliver flow, volume, and pressure^{19,20}
3. The cycling off criteria (phase cycling variable), or when the ventilator stops assisting inspiratory effort and lets the patient exhale spontaneously^{16,17}

Features of ventilators, such as blowers and inspiratory, expiratory, and positive end-expiratory pressure (PEEP) valves, are also important in determining the interaction between patient and ventilator.²¹⁻²⁴

To unload the respiratory muscles, restore sufficient gas exchange, and relieve the patient from dyspnea, the clinician has two options: 1) total ventilator-controlled mechanical support; or 2) partial patient-controlled support.

Total Ventilator-Controlled Mechanical Support

In this mode, the patient's breathing pattern is totally controlled by the ventilator. The pressure generated by the respiratory muscles is abolished. Although this condition can be achieved in some conscious patients (i.e., patients with neuromuscular diseases), it usually requires sedation and/or paralysis. Flow, volume, and pressure are imposed by the ventilator, and the patient's breathing pattern is totally replaced by that of the ventilator. The risk of patient-ventilator asynchrony is therefore abolished, but there are potential risks associated with sedation and paralysis,²⁵ including respiratory muscle atrophy,²⁶ lung damage due to overdistention,²⁷ patient discomfort,²⁸ and difficulty weaning after prolonged controlled mechanical ventilation.¹

Partial Patient-Controlled Mechanical Support

With this mode, spontaneous breathing activity is partially preserved,²⁹ with a decreased need for sedation and paralysis.³⁰ The ability to restore gas exchange, unload respiratory muscles, and relieve patient dyspnea with partial patient-controlled mechanical support, therefore, depends on the absence of patient-ventilator asynchrony.³¹

Although there are no well-accepted definitions, patient-ventilator asynchrony is common, albeit often unrecognized, underestimated, and inappropriately treated.^{3-5,18,31-33} Patient-ventilator asynchrony appears whenever a mismatch between the three physiologic variables characterizing spontaneous breathing (ventilatory drive, ventilatory requirements, and the duration and ratio of inspiratory time to total breath cycle duration) and the three technologic variables

FIGURE 61-1 ■ Neuroventilatory coupling. Under normal conditions, as well as at the onset of acute respiratory failure, spontaneous contraction of respiratory muscles suddenly generates flow and volume. The slope of the relationship between effort and ventilatory output is conditioned by the contractile properties of the respiratory muscles and impedance of the respiratory system. When positive pressure is applied to assist the action of breathing in the most common modes of mechanical ventilation, the coupling between effort and output is compromised. During volume targeted assist-control ventilation (ACV), flow and volume remain constant despite changes in muscle contraction. During pressure support ventilation (PSV), despite a sort of coupling between inspiratory effort and ventilatory output, any increase in respiratory impedance decreases the amount of delivered flow and volume. VT, tidal volume.

characterizing ventilator function (trigger function, the gas delivery algorithm [controlled variable], and cycling criteria) occurs.

RESPIRATORY DRIVE-VENTILATOR TRIGGER ASYNCHRONY

During partial ventilatory assistance, the inspiratory synchronization system (inspiratory trigger) detects any patient inspiratory effort and activates a mechanical act. Therefore, inspiratory effort is tracked to couple the patient's effort with the delivery of pressure, flow, or volume. The goal of a good inspiratory trigger is to reduce the duration and intensity of the muscular effort as much as possible prior to the initiation of a mechanically supported breath.³⁴ It has been suggested that a trigger (independent of the algorithm) must have a response time of less than 100 ms. However, the inspiratory effort necessary to trigger a breath may be a significant part of the total inspiratory effort, representing 17% and 12% of the total inspiratory effort during pressure and flow triggering, respectively.^{19,20,13,14,15,16,17,18,21,32,33} Aslanian and coworkers found that although the time required for triggering was 43% shorter and the effort during the time of triggering was 62% less with flow triggering than with pressure triggering, effort for the post-triggering phase was equivalent for both these modalities.³⁵ Therefore, the clinical benefit of flow triggering appears to be much less relevant than commonly stated.³

Inspiratory phase asynchrony may be due to problems with inspiratory triggering, and this can be correlated with the respiratory drive.

FIGURE 61-2 ■ Representative tracings show the interaction between patient effort and triggering of the ventilator. The delay between the beginning of inspiratory muscle activity (dotted line) and the beginning of mechanical inflation (solid line) can cause an inspiratory phase asynchrony. Flow: flow generated at airway opening; Paw: the pressure applied at airway opening; Pes: esophageal pressure.

Phase lag quantifies the delay between the start of inspiratory muscle activity and the beginning of mechanical inflation (Fig. 61-2).^{3,10,11} The presence of a threshold load, such as dynamic intrinsic PEEP, may further complicate the patient-ventilator interaction during the triggering phase.¹⁹ Giuliani et al. suggests that effort during triggering determines patient effort during the remaining portion of inspiration.³⁶ Leung and coworkers demonstrated that the higher the level of ventilator-applied pressure, the lower the respiratory drive, but the longer the time required to trigger the ventilator. As a result, respiratory muscles generate smaller inspiratory swings in intrathoracic pressure but over a longer inspiratory time.² Another problem is related to the fact that pressure is mostly detected inside the ventilator. Therefore, any resistive load (e.g., endotracheal tube or upper airways during NIV) reduces the ventilator trigger sensitivity in response to patient effort.¹⁸

Auto-triggering can be defined as a mandatory breath delivered in the absence of a patient's inspiratory effort.²² Monitored breaths on the ventilator are higher than those initiated by the patient. Auto-triggering can be generated by too sensitive inspiratory triggers, air leaks, or an external signal, such as heart rate or water in the respiratory circuit.

Ineffective triggering is due to the ventilator's inability to detect the patient's "request" for an assisted breath despite substantial inspiratory effort (Fig. 61-3). This phenomenon usually occurs with high levels of ventilator assistance and short expiratory times. Mechanical characteristics that may induce ineffective triggering include low elastance, high resistance, and intrinsic PEEP. Ineffective triggering is not correlated to an increase in the patient's inspiratory effort.⁴ The application of external PEEP below the intrinsic PEEP level can reduce the inspiratory effort required to trigger the ventilator.³⁷

Double triggering is defined as the presence of two inspiratory cycles separated by a very short expiratory time and may result in breath stacking. Double triggering can be elicited by a high patient ventilatory demand causing two breaths with a limited expiratory phase due to a too short of a ventilator inspiratory time (Ti) compared to the patient's neural time. This problem can be addressed by increasing Ti in time-cycled mode, by adjusting the expiratory threshold time in the flow-cycled mode, or optimizing pressure rise time (i.e., the time taken to reach the pressure set on the ventilator).³⁸

FIGURE 61-3 ■ Representative tracings show ineffective triggering due to ventilator's inability to detect patient's "request" for an assisted breath. A substantial inspiratory effort (arrows) generates only a bump in the flow and pressure tracings instead of a mandatory assisted breath. Flow: flow generated at airway opening; Paw: the pressure applied at airway opening; Pes: esophageal pressure.

Reverse-triggering is a recently discovered form of neuromechanical coupling with potentially important clinical consequences in heavily sedated patients.³⁹ In this case, contrary to the usual triggering sequence (patient's effort switching on the ventilator-driven breath), diaphragmatic muscle contractions are triggered by ventilator insufflations.

New trigger algorithms aim to improve the patient-ventilator interaction during sudden changes in flow or respiratory rate and the presence of air leaks during NIV. Volume triggers, triggers linked to flow waveform algorithms, combining pressure and flow signals in the same trigger algorithm, or using both pressure and flow triggers have been developed. However, all inspiratory trigger drawbacks may be overcome by using a neural trigger obtained using a dedicated nasogastric tube with multiple arrays of electrodes placed in the distal esophageal portion.^{8,40,41}

VENTILATORY REQUIREMENT-GAS DELIVERY ASYNCHRONY

Gas delivery asynchrony occurs when ventilator-delivered flow, volume, and pressure are insufficient to meet the patient's ventilatory demand. Ward and coworkers demonstrated that increasing the flow rate could be used as a means of reducing the patient's respiratory drive and active respiratory muscle work,¹³ although this may exert an excitatory effect on the respiratory rate and the rate of rising of inspiratory muscle activity.^{3,16,17,42-48} Laghi and colleagues demonstrated that the imposed inspiratory time during mechanical ventilation determined respiratory frequency independent of inspiratory flow and tidal volume.¹⁶ Pressure-targeted breaths may more effectively match the patient's ventilatory requirements because the flow is the dependent variable during constant pressure delivery. In addition, rapid pressurization of the airways is coupled with high inspiratory flow only at the beginning of inspiration, thus reproducing the physiologic flow profile.⁴⁹ However, during a pressure-targeted breath, the setting for the time of pressure increase may influence the patient-ventilator interaction because its modification determines the dependent flow output.^{50,51}

INSPIRATORY TIMING-VENTILATOR CYCLING ASYNCHRONY

A breath can be pressure, time, volume, or flow-cycled.⁵¹ While volume and pressure cycling are no longer used, a breath is defined as time-cycled when it is terminated after a given preset inspiratory time is reached (e.g., pressure- or volume-controlled time-cycled breaths) or as flow-cycled when the generated inspiratory flow decays from its peak of a fixed percentage (e.g., PSV mode).

Ventilator-patient asynchrony occurs when the patient is trying to exhale, but the ventilator is still delivering gas.^{35,52,53} Parthasarathy and coworkers demonstrated that prolonging mechanical inflation into neural expiration reduces the time available for unopposed exhalation, resulting in the need for a greater inspiratory effort to trigger the ventilator.⁵² Younes and colleagues showed that the delayed opening of the exhalation valve in ventilator-dependent patients exacerbates dynamic hyperinflation.⁵⁴

In patients ventilated with a time-cycled breath, expiratory phase asynchrony occurs when the patient's neural inspiratory time is shorter or longer than the ventilator inflation time. For proper cycling of the ventilator and optimal patient-ventilator synchrony, the patient's inspiratory flow and ratio of inspiratory time-to-total breath cycle duration must be tracked.

During flow-cycled breaths as in pressure-support mode, inspiratory time is determined exclusively by the time taken for the exponentially declining flow to reach the flow threshold value (when cycling between inspiration and expiration occurs).^{32,55} The inspiratory flow threshold value, also called the *expiratory trigger*, thus controls the inspiration-to-expiration switch in these modalities under the postulate that the very end of patient inspiration is tracked by inspiratory flow decay.^{50,56}

The goal of these ventilatory modes is to optimize the synchronization between spontaneous patient inspiratory time and ventilator inspiratory time. However, for proper cycling-off and optimal patient-ventilator synchrony, the ventilator must always track the patient's inspiratory flow.^{52,57,58}

PATIENT-VENTILATOR ASYNCHRONY DURING PRESSURE SUPPORT VENTILATION

Three phases may influence patient-ventilator interaction during PSV: 1) the threshold value of inspiratory flow decay (expiratory trigger); 2) the pressure ramp (pressure slope); and 3) the level of PSV.

(1) The expiratory trigger sensitivity can be fixed (default at 25% of peak flow) or can vary from 1% to 90% or 5 to 25 L/min in some old ventilator software (Fig. 61-4).⁵⁹ It can also be linked to algorithms where there is a ranking logic of expiratory cycling criteria that links cycling to expiration. Setting the expiratory trigger at a higher percentage of peak inspiratory flow (i.e., 40% to 70% of decay of the peak inspiratory flow) in patients with obstructive pulmonary disease improves patient-ventilator synchrony and reduces inspiratory muscle effort.⁶⁰ In addition, the modification of the cycling-off criteria may have a beneficial effect on reducing the dynamic hyperinflation and inspiratory effort in chronic obstructive pulmonary disease patients, especially at low levels of pressure support.⁶¹

The proper adjustment of the expiratory trigger threshold may be important in improving patient-ventilator synchrony and in decreasing the work of breathing during acute lung injury. Unlike in obstructive pulmonary disease, setting the threshold at 5% of the peak inspiratory flow might be the optimal value for patients with acute respiratory distress syndrome or acute lung injury.⁶² Indeed, Chiumello et al. found that in patients recovering from acute lung injury during PSV at 15 cm H₂O, the lowest cycling-off criteria reduced the respiratory rate and increased the tidal volume without modifying the work of breathing.⁶³

The expiratory sensitivity setting is crucial when ventilators are used to deliver NIV since air leaks may cause an abnormal prolongation of the mechanical inspiratory time at the expense of a patient's expiration that results in shortened and hampered expiration (inspiratory hang-up) (Fig. 61-5).⁶⁴⁻⁶⁹

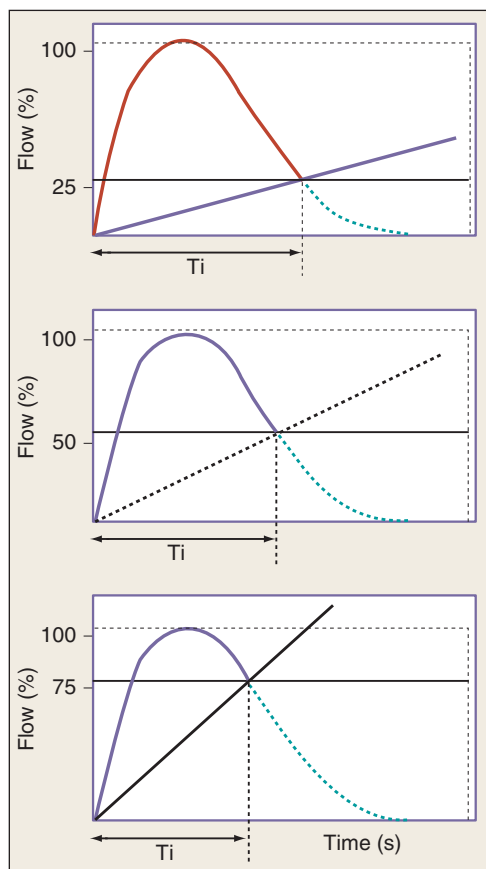

FIGURE 61-4 ■ Representative tracings show different settings for expiratory trigger sensitivity on a flow-time plot. *Top to bottom*, Expiratory trigger set at 25%, 50%, and 75% of peak flow. Ventilator inspiratory time is influenced by preset flow expiratory trigger sensitivity, at which point the ventilator switches to expiration.

(2) The setting of the pressure rise time (pressure slope) can affect the expiratory threshold by modifying the dependent inspiratory flow.^{63,70-73} Although there is some evidence that rapid pressure rise times might reduce a patient's work of breathing,⁷¹ a fast pressure increase may lead to particularly high peak inspiratory flow, which may then cause premature termination of inspiration when the fixed percentage criterion for expiratory cycling is reached (Fig. 61-6).^{18,61,73}

Prinianakis et al. assessed the effects of varying the rate of pressure change during noninvasive PSV on the breathing pattern of patients with COPD, as well as inspiratory effort, arterial blood gases, tolerance to ventilation, and the amount of air leakage. No significant changes were observed in breathing pattern and arterial blood gases between the differing amounts of pressure change, but the pressure-time product of the diaphragm, an estimate of its metabolic consumption, significantly decreased with increasing the rate of pressurization. Interestingly, air leaks increased, and the patients' tolerance of ventilation was significantly poorer with the fastest rate of pressure change.⁷⁴

(3) During NIV, the pressure support level affects patient-ventilator interactions, mainly through effects on the generation of air leaks.^{9,65} Since air leaks may determine modifications in the inspiratory flow profile (see above), their reduction by lowering to a PSV level of 1 or 2 cm H₂O has been demonstrated to improve patient-ventilator asynchrony.⁹

FIGURE 61-5 ■ Representative record of air leaks during noninvasive face mask pressure support ventilation. The presence of air leaks causes prolonged ventilator inspiratory time (arrows). Flow, flow generated at airway opening; Paw: the pressure applied at airway opening; Pes: esophageal pressure.

FIGURE 61-6 ■ Representative tracings show different pressure rise time sensitivities on a flow-time plot. *Left to right*, Pressure rise time set at 90%, 60%, and 30% of maximal pressurization time. Ventilator inspiratory time (shaded area) is influenced by preset pressure-slope sensitivity that generates a different peak inspiratory flow. Paw, the pressure applied at airway opening; Flow, flow generated at airway opening.

In conclusion, dyssynchrony at the termination of a PSV breath can be corrected by varying the cycling-off criteria (e.g., the expiratory trigger threshold) or modulating the inspiratory flow (e.g., modifying the pressure slope or varying the set pressure level).⁹ Automated modes designed to achieve an optimal expiratory cycling during PSV are available but deserve further investigation.⁷⁵⁻⁷⁶

TOTAL PATIENT-CONTROLLED MECHANICAL SUPPORT

Optimization of patient-ventilator interactions can be obtained only by continuous matching between the triggering, flow delivery, cycling functions of the ventilator and the patient's ventilatory drive, spontaneous inspiratory flow demand, and ratio of inspiratory time to the total breath cycle. This implies a continuous measurement of physiologic variables and continuous adaptation of the ventilator to the spontaneous variations in these variables. Future development in ventilator technology should be oriented toward systems with the capability to automatically interface between physiologic parameters and ventilator output. Such technology will be based on closed-loop algorithms able to achieve total patient-controlled mechanical support.⁴

The design features of an automatic control system in a mechanical ventilator include (1) what activates the system (the input); (2) what the system produces (the output); and (3) the protocol used to link input and output (the controlling algorithm). In a closed-loop system, the output will activate and condition the input. When changes in output are opposite to changes in input, the closed loop is said to be negative. The closed loop is positive when variations in output mirror variations in input. The most common example of a negative closed-loop control system in a clinical setting is the ventilator humidifier. In this case, the input is the temperature inside the chamber, and the output is the temperature of the gas being delivered to the patient. The controlling algorithm is designed to keep the latter constantly above a value set by the operator. If the output (i.e., the temperature of gas delivered to the patient) is lower than the preset level, the algorithm will increase the input (i.e., the temperature in the chamber). If the output is higher than the preset level, the algorithm will decrease the input. Closed-loop systems are hence able to stabilize and limit the performance of a mechanical system.

In the case of acute respiratory failure, the patient is unable to provide sufficient output (i.e., minute ventilation). Therefore, the ventilator should be able to detect the input from the patient and continuously adapt the output. If the input is increasing (i.e., ventilatory requirements are increasing), the ventilator will increase the output (i.e., apply more positive pressure). If the input is decreasing (i.e., ventilatory requirements are decreasing), the ventilator will decrease the output (i.e., apply less positive pressure). The controlling closed loop eventually applied by the ventilator must be positive. Positive closed-loop control systems are inherently unstable in the sense that they tend to: (1) "run away" with ventilatory assistance. If the pressure generated by the ventilator is higher than the pressure required to offset the passive properties of the respiratory system, the ventilator will continue to deliver flow and volume while the patient stops his or her inspiratory effort and tries to initiate expiration; and (2) "extinguish" ventilatory assistance. If the patient does not produce any inspiratory effort, the ventilator will not produce any ventilatory support.

Based on closed-loop algorithms, new modes of mechanical ventilation have been proposed. Such approaches represent modifications of PSV and are characterized by the patient's ability to control the amount of assistance provided by the ventilator. They are differentiated by the patient-related variables used to close the loop.

PROPORTIONAL ASSISTED VENTILATION (PAV), PROPORTIONAL PRESSURE SUPPORT (PPS), AND PROPORTIONAL ASSISTED VENTILATION PLUS (PAV+)

During PAV and PPS, the ventilator generates pressure in proportion to the patient-generated flow and volume^{77,78}; the ventilator amplifies

patient effort without imposing any ventilatory or pressure targets; and ventilator-generated pressure rises as long as inspiratory muscle effort is produced by the patient. During these modes of mechanical support, the clinician adjusts the percentage of flow-assisted or volume-assisted ventilation after determining the patient's resistance and elastance with the goal of reducing the load imposed by the patient's inspiratory workload.^{79,80,81} Despite the exciting potential of these techniques⁸¹⁻⁸⁴ applied either invasively or noninvasively,⁷⁵⁻⁹³ no large-scale studies have demonstrated an improvement in patient outcome with PAV or PPS compared with other modes of ventilation. Several studies performed during invasive ventilation showed that PAV improves patient-ventilator synchrony at the start of inspiration^{32,86,88} but not necessarily at the end.⁷⁸⁻⁸⁶

Compared with PAV, PAV+ provides a continuous measurement of the patient's elastance and resistance according to the method described by Younes and coworkers.^{79-81,89-93} This option requires that the physician set only a given percentage of the overall pressure gain level. During invasive ventilation, PAV+ appears to reduce the incidence of patient-ventilator asynchronies considerably compared to conventional PAV⁹⁴ (Fig. 61-7). When compared to PSV, PAV+ decreases the setting time and fastens changes in sedative doses.⁹⁵

NEURAL-ADJUSTED VENTILATORY ASSISTANCE (NAVA)

With NAVA, the electrical activity of the diaphragm is measured using an electrode array inserted into a nasogastric tube placed in the lower esophagus; this information is then used to control the ventilator to generate flow, volume, and pressure by applying pressure in proportion to diaphragm electrical activity.^{8,38,39,96,97} A representative tracing of NAVA is shown in Fig. 61-8. With NAVA, therefore, the patient retains full control of the breathing pattern.⁹⁸ Unlike with the proportional mode described earlier, estimates of respiratory mechanics are not needed. With NAVA, the patient's respiratory center controls the assisted positive breaths in all phases of the ventilation cycle, from triggering to cycling-off of inspiration. Any change in patient ventilatory output is matched breath by breath by the ventilator, even in the presence of variations in respiratory mechanics.

NAVA has been shown to decrease ineffective efforts (trigger asynchrony) and premature and delayed cycling (cycle asynchrony) compared to a pressure-controlled flow-cycled ventilation (i.e., PSV).⁹⁹⁻¹⁰¹ Furthermore, Vignaux et al. demonstrated that, compared to pressure support NIV, NAVA improves patient-ventilator synchrony both by reducing trigger delay and the number of asynchrony events.¹⁰² NAVA also appears to improve patient-ventilator synchrony during helmet ventilation.¹⁰³ Finally, NAVA has one major advantage compared to PAV since air leaks do not interfere with its correct functioning.¹⁰⁴

ADAPTIVE SUPPORT VENTILATION

Compared to PAV and NAVA, adaptive support ventilation is an assist time-limited, pressure-targeted mode of ventilation (pressure-controlled ventilation) that relies on a negative closed-loop system of regulating ventilator settings in response to changes in both respiratory impedance (elastance and resistance) and the patient's spontaneous efforts.¹⁰⁵ The basic principle relies on the work of Otis and coworkers¹⁰⁶ and Mead,⁶ demonstrating that for a given level of minute alveolar ventilation, there is a respiratory rate that is least costly regarding respiratory work. With adaptive support ventilation, the operator enters the patient's body weight and sets the desired minute ventilation. The expiratory time constant is determined by analysis of the expiratory flow-volume curve.¹⁰⁷ Adaptive support ventilation thus adjusts for inspiratory pressure, inspiratory-expiratory time ratio, and the mandatory respiratory rate to maintain the target minute ventilation and respiratory rate within a framework designed to avoid both rapid, shallow breathing and excessive inflation volumes. Spontaneous breathing triggers either a pressure-controlled or a spontaneous breath with inspiratory pressure support, the level of which is adjusted to meet the target respiratory rate-tidal volume combination.

FIGURE 61-7 ■ Representative tracing of flow (Flow), airway pressure (P_{aw}), esophageal pressure (P_{eso}), gastric pressure (P_{ga}), and transdiaphragmatic pressure (P_{di}) during PAV+ ventilation. Directional arrow (bottom) going from left to right shows that the gain is reduced from 95% to 50% with a subsequently increased inspiratory effort. Dotted arrows (top) indicate the measurement of respiratory mechanics automatically computed by the ventilator.

FIGURE 61-8 ■ Representative tracing of flow (Flow), airway pressure (P_{aw}), esophageal pressure (P_{eso}), and transdiaphragmatic pressure (P_{di}) during NAVA ventilation. The two dotted lines define the beginning and end of the patient's inspiratory effort.

KEY POINTS

1. Patient-ventilator asynchrony is common during mechanical ventilatory support. It is often unrecognized, underestimated, and inappropriately treated in a clinical setting.
2. Patient-ventilator asynchrony occurs when the three physiologic variables of the patient's breathing pattern, ventilatory drive, driving, and timing components of the breathing cycle, do not match ventilator trigger, ventilator-delivered flow, and ventilator cycling criteria.
3. Clinical optimization of patient-ventilator interactions can be obtained only by continuously matching the triggering, flow delivering, and cycling functions of the ventilator with the patient's physiologic variables.
4. Optimization of patient-ventilator interactions during invasive or noninvasive ventilation implies a continuous measurement of physiologic variables and continuous adaptation of the ventilator to the spontaneous variations in these physiologic variables.
5. Future developments in ventilator technology should be oriented toward a system with the capability to interface automatically between physiologic parameters and ventilator outputs. Such technology will be based on closed-loop algorithms able to achieve total patient-controlled mechanical support.

- Laghi F, Karamchandani K, Tobin MJ. Influence of ventilator settings in determining respiratory frequency during mechanical ventilation. *Am J Respir Crit Care Med* 1999;160(5):1766-70.
These authors found that during the assist-control mode, ventilator inspiratory time can determine respiratory frequency independently of inspiratory flow and tidal volume.
- Leung P, Jubran A, Tobin MJ. Comparison of assisted ventilator modes on triggering, patients' effort, and dyspnea. *Am J Respir Crit Care Med* 1997;155(6):1940-8.
This study found that when receiving assist-control ventilation or high levels of pressure support, one-quarter to one-third of a patient's inspiratory efforts may fail to open the inspiratory valve triggering the machine. The number of ineffective triggering attempts increases in proportion to the level of ventilatory assistance and is not correlated with the magnitude of inspiratory effort at a given level of assistance.
- Parthasarathy S, Jubran A, Tobin MJ. Cycling of inspiratory and expiratory muscle groups with the ventilator in airflow limitation. *Am J Respir Crit Care Med* 1998;158(5):1471-8.
These authors found that the continuation of a mandatory mechanical breath into neural expiration was associated with a waste of inspiratory effort, defined as failure of the subsequent inspiratory attempt to trigger the ventilator.
- Parthasarathy S, Tobin JM. Effect of ventilator mode on sleep quality in critically ill patients. *Am J Respir Crit Care Med* 2002;166(11):1423-9.
These authors found that inspiratory assistance during pressure support causes hypoxemia, which combined with a lack of a backup rate and wakefulness drive can lead to central apneas and sleep fragmentation, especially in patients with heart failure. A backup rate, as during assist-control volume-targeted ventilation, prevents the development of apneas and perhaps decreases arousals.
- Sinderby C, Navalesi P, Beck J, et al. Neural control of mechanical ventilation in respiratory failure. *Nat Med* 1999;5(12):1433-6.
This article describes a completely new mode of detecting inspiratory effort, based on the measurement of electrical activity of the diaphragm using an electrode array inserted into a nasogastric tube and placed in the lower esophagus. The output generated from the electrodes, filtered out for, is used to control the ventilator that finally generates the respiratory output.
- Tobert DG, Simon PM, Stroetz RW, Hubmayr RD. The determinants of respiratory rate during mechanical ventilation. *Am J Respir Crit Care Med* 1997;155(2):485-92.
The authors examined the rate response of eight normal volunteers during both quiet wakefulness and non-rapid-eye-movement (non-REM) sleep in the setting of mechanical ventilation through a nasal mask in an assist-control mode with a machine backup rate of 2 breaths per minute. They found that both tidal volume and inspiratory flow settings affect the respiratory rate and can affect carbon dioxide homeostasis. During non-REM sleep, hypoxemia resulted in wasted ventilator trigger efforts. Thus, ventilator settings appropriate for wakefulness may cause ventilatory instability during sleep.
- Younes M, Webster K, Kun J, et al. A method for measuring passive elastance during proportional assist ventilation. *Am J Respir Crit Care Med* 2001;164(1):50-60.
A noninvasive method to continuously measure elastance of the respiratory system during proportional assisted ventilation is described.

Noninvasive ventilation is defined as the provision of ventilatory assistance to the lungs without an invasive artificial airway. Noninvasive ventilators consist of a variety of devices, including negative- and positive-pressure ventilators. Until the early 1960s, negative-pressure ventilation in the form of tank ventilators was the most common type of mechanical ventilation outside of the anesthesia suite.¹ However, during the Copenhagen polio epidemic of 1952, it was observed that the survival rate improved when patients with respiratory paralysis were treated with invasive positive-pressure anesthesia devices. Subsequently, invasive positive-pressure mechanical ventilation gradually became the preferred means of treating acute respiratory failure.² Negative-pressure and other so-called body ventilators remained the mainstay of ventilatory support for patients with chronic respiratory failure until the mid-1980s.¹

With improving mask and ventilator technology and the many advantages over negative-pressure ventilation,¹ noninvasive positive-pressure ventilation (NIPPV) displaced negative-pressure ventilation as the treatment of choice for chronic respiratory failure in patients with neuromuscular and chest wall deformities.³ Over the past 30 years, noninvasive ventilation has spread from the outpatient to the inpatient setting, where it is used to treat acute respiratory failure. Studies involving large clinical databases show that NIPPV use for patients with acute respiratory failure (ARF) due to COPD, as well as non-COPD diagnoses, increased several fold during the first decade of the millennium.⁴ A recent survey in Massachusetts found that NIPPV is used very frequently in the acute care setting, constituting up to 40% of initial ventilator starts.⁵ This chapter discusses the rationale for the increased use of NIPPV in critical care, as well as appropriate indications, practical applications, and monitoring.

RATIONALE

The most important advantage of noninvasive ventilation is the avoidance of complications associated with invasive mechanical ventilation. These include upper airway trauma, the bypass of the upper airway defense mechanisms, increased risk of nosocomial pneumonia, and interference with upper airway functions, including the ability to eat and communicate normally.⁶ By avoiding airway intubation, noninvasive ventilation leaves the upper airway intact, preserves airway defenses, and, during breaks, allows patients to eat and vocalize normally, as well as expectorate secretions. Compared with invasive mechanical ventilation, noninvasive ventilation reduces infectious complications, including pneumonia, sinusitis, and sepsis.⁷⁻⁹ Strengthening the rationale for its use is evidence that noninvasive ventilation lowers the morbidity and mortality rates of selected patients with acute respiratory failure and may shorten hospital length of stay or avoid hospitalization altogether,¹⁰ thus reducing costs.

The main indication for mechanical ventilatory assistance is to treat respiratory failure, either type 1 (hypoxemic), type 2 (hypercapnic), or both. [Figure 62-1](#) shows that airspace collapse, surfactant abnormalities, and airway narrowing and closure contribute to ventilation-perfusion abnormalities and shunt, which cause hypoxemia. By opening the collapsed air spaces and narrowed airways, positive airway pressure reduces shunt and improves ventilation-perfusion relationships, ameliorating hypoxemia. In addition, positive airway pressure can reduce the work of breathing by improving lung compliance as a

consequence of opening collapsed air spaces. Another potential benefit of positive airway pressure is enhanced cardiovascular function via the afterload-reducing effect of increased intrathoracic pressure. Conversely, deleterious cardiovascular effects may occur if the preload-reducing effect outweighs the afterload-reducing effect, as may be observed in patients with reduced intravascular fluid volume.

MECHANISMS OF ACTION

[Figure 62-2](#) shows the pathophysiologic mechanisms that contribute to ventilatory failure. Increased airway resistance, reduced respiratory system compliance, and intrinsic positive end-expiratory pressure (PEEP) contribute to the increased work of breathing, predisposing patients to respiratory muscle fatigue. In patients with chronic obstructive pulmonary disease (COPD), the increased radius of the diaphragmatic curvature, which increases muscle tension and thereby increases impedance to blood flow, exacerbates the situation. By counterbalancing intrinsic PEEP with extrinsic PEEP and by augmenting tidal volume with intermittent positive-pressure ventilation, NIPPV reduces the work of breathing and avoids the vicious circle leading to respiratory failure. Work of breathing measurements, including transdiaphragmatic pressure, diaphragmatic pressure-time product, and diaphragmatic electromyographic amplitude, are all decreased when NIPPV is delivered to patients with exacerbations of COPD. In such patients, continuous positive airway pressure (CPAP) and pressure-support ventilation (PSV) both reduce the work of breathing, but the combination of the two (PSV + PEEP) is more effective than either alone.¹¹

INDICATIONS

A number of causes of acute respiratory failure are now considered appropriate for noninvasive ventilation therapy and are listed in [Box 62-1](#). Evidence supporting these indications is rated and briefly discussed here; guidelines for patient selection are discussed later.

Airway Obstruction

Chronic Obstructive Pulmonary Disease

A number of randomized controlled trials^{12,13} and meta-analyses¹⁴ have consistently shown that compared with conventional therapy, NIPPV improves vital signs, gas exchange, and dyspnea scores; reduces the rates of intubation, morbidity, and mortality; and shortens hospital length of stay in patients with moderate to severe exacerbations of COPD. Thus, NIPPV is considered the ventilatory mode of choice in selected patients with acute exacerbations of COPD. Some studies suggest that the addition of heliox to NIPPV further improve the work of breathing and gas exchange during COPD exacerbations,¹⁵ but a subsequent multicenter trial found no improvement in other outcomes compared with noninvasive ventilation alone.¹⁶

Asthma

Uncontrolled studies have reported improvements in gas exchange and low rates of intubation after the initiation of NIPPV in patients with severe asthma attacks. Two controlled trials have demonstrated a more rapid improvement in expiratory flow rates with NIPPV,^{17,18} and one

ARDS, acute respiratory distress syndrome; COPD, chronic obstructive pulmonary disease; CPAP, continuous positive airway pressure.

showed a decreased hospitalization rate in acute asthma patients treated with noninvasive ventilation compared with a sham mask.¹⁸ Neither study was powered adequately to assess intubation or mortality rates. Nonetheless, these data support a trial of NIPPV in asthmatics responding poorly to initial bronchodilator therapy. Noninvasive ventilation can be combined with continuous nebulization and heliox, although the added value of these latter therapies has not been established in controlled trials.

Cystic Fibrosis

Uncontrolled studies indicate that noninvasive ventilation is useful to stabilize gas exchange in the treatment of acute episodes of respiratory failure in end-stage cystic fibrosis patients and can serve as a bridge to transplantation.¹⁹

Obesity Hypoventilation Syndrome

Acute hypercapnic respiratory failure related to obesity hypoventilation is becoming more prevalent given the increasing obesity rates in the general population. A single-center prospective observational study was conducted to examine the use of NIV in these patients. Using COPD patients with acute hypercapnic respiratory failure for comparison, the authors found no change in the rate of NIV failure between the two groups and found lower rates of late NIV failure, readmission to the ICU, and ICU and hospital mortality in the OHS group. Their conclusion was that NIV can be safely and efficaciously used in acute hypercapnic respiratory failure related to OHS in the ICU.²⁰

Upper Airway Obstruction

Anecdotally, noninvasive ventilation can be used to treat patients with upper airway obstruction, such as that caused by glottic edema following extubation. In this situation, noninvasive ventilation can be combined with aerosolized medications or heliox, but no controlled trials have demonstrated the efficacy of this approach. If therapy with noninvasive ventilation is considered, patients should be selected with great caution and monitored closely, because upper airway obstruction can lead to precipitous deterioration. The use of noninvasive ventilation in patients with tight, fixed upper-airway obstruction is inappropriate because it delays the institution of definitive therapy.

Hypoxemic Respiratory Failure

Hypoxemic respiratory failure is defined as severe hypoxemia (arterial oxygen partial pressure-inspired oxygen fraction ratio <200) combined with a respiratory rate above 35 breaths per minute and a non-COPD diagnosis including acute pneumonia, acute lung injury (ALI), acute respiratory distress syndrome (ARDS), pulmonary edema, or trauma. Controlled trials of noninvasive ventilation to treat patients with acute hypoxemic respiratory failure have shown statistically significant reductions in the rate of intubation, the length of hospital stay, the incidence of infectious complications,^{8,21} and in one study, ICU mortality.²¹ However, because of the heterogeneity of causes, these studies fail to demonstrate that all patient subgroups with hypoxemic respiratory failure benefit equally from noninvasive ventilation. Furthermore, when patients are stratified according to the acuity of illness, patients with a simplified acute physiologic score (SAPS II) less than 35 fare considerably better with NIPPV than do those with higher scores.²² Thus, the selection of patients with less severe disease is likely to enhance the success of NIPPV in treating hypoxemic respiratory failure, and studies that examine individual subgroups within the larger category are likely to be more useful clinically.

Pneumonia

One controlled trial showed that noninvasive ventilation in patients with severe community-acquired pneumonia lowers the rate of endotracheal intubation and shortens the length of ICU stay compared with conventional therapy; however, a subgroup analysis revealed that the benefits occurred only in patients with underlying COPD.²³ No benefit was apparent in the non-COPD patients with severe pneumonia. A subsequent uncontrolled trial in non-COPD patients with severe pneumonia found that two-thirds of such patients treated with noninvasive ventilation eventually required intubation.²⁴ Although the latter authors deemed a trial of noninvasive ventilation in non-COPD patients with severe pneumonia to be a reasonable approach, controlled data to support such a recommendation are currently lacking.

Immunocompromised States

The dismal prognosis of invasively ventilated immunocompromised patients makes noninvasive ventilation an appealing ventilatory mode, with its demonstrated ability to decrease the rate of nosocomial infection.⁷ Earlier studies in both solid organ transplantation patients²⁵ and neutropenic patients (most of whom had hematologic malignancies)²⁶ who developed acute hypoxemic respiratory failure, noninvasive ventilation reduced the rate of intubation, nosocomial infection, and ICU mortality compared with conventional therapy. However, more recent studies suggest that the benefit of NIPPV is difficult to demonstrate, and one adequately powered randomized controlled study comparing NIPPV to oxygen therapy showed no reduction in intubation or mortality rate or length of hospital stay.²⁷ In immunocompromised patients with *Pneumocystis carinii* pneumonia due to the acquired immunodeficiency syndrome (AIDS), noninvasive ventilation yields benefits compared to invasive mechanical ventilation in physiologically and demographically matched patients.²⁸ Thus, current recommendations suggest reserving NIPPV for milder cases of acute respiratory failure in immunocompromised patients and resorting to intubation without undue delay if progressive deterioration occurs.^{29,30}

Acute Respiratory Distress Syndrome

ARDS patients with severe oxygenation defects and multiple organ system dysfunctions should undergo prompt intubation and invasive ventilation as the preferred modality. A prospective cohort study³¹ using noninvasive ventilation as a “first-line” intervention for ARDS found that ventilator-associated pneumonia and mortality were greatly reduced when patients succeeded rather than failed noninvasive ventilation, and a simplified acute physiology score of 34 or less and PaO_2/FiO_2 above 175 within the first hour predicted the success of noninvasive ventilation. Thus, noninvasive ventilation could be considered in

ARDS patients meeting these criteria, but such patients must be monitored closely to avoid any delay in intubation if deterioration occurs.

Acute Cardiogenic Pulmonary Edema

Meta-analyses of randomized, controlled trials demonstrated that compared with oxygen therapy, CPAP (though not a true mode of ventilatory support) is highly effective at relieving respiratory distress, improving gas exchange, and averting intubation when used to treat patients with acute cardiogenic edema.^{32,33} Inspiratory assistance combined with expiratory pressure can reduce the work of breathing and alleviate respiratory distress more effectively than CPAP alone. Moreover, several uncontrolled trials and two controlled trials found that noninvasive ventilation and CPAP are equally effective in improving vital signs and avoiding intubation. The current recommendation is to use CPAP alone or noninvasive ventilation as an initial therapy; if CPAP is used initially, inspiratory pressure support should be added if the patient has persistent hypercapnia or dyspnea.³³

Postoperative Respiratory Failure

NIPPV and CPAP alone have been studied in postoperative patients who develop respiratory failure following various kinds of surgeries. In particular, it reduces extravascular lung water and improves lung mechanics and gas exchange following coronary artery bypass surgery.³⁴ Controlled trials show that CPAP or NIV averts postoperative complications compared to oxygen supplementation after high-risk procedures like thoracoabdominal aortic procedures³⁵ or abdominal surgery.³⁶ Noninvasive ventilation improves oxygenation, reduces the need for reintubation, lowers the mortality rate after lung resectional surgery,³⁷ and enhances pulmonary function after gastropasty.³⁸ Thus, noninvasive ventilation should be considered in selected postoperative patients at a high risk of pulmonary complications or with frank respiratory failure, especially in the setting of underlying COPD or pulmonary edema.

Trauma and Burns

Trauma patients develop respiratory failure for a multitude of reasons, but some have chest wall injuries, such as flail chest or mild acute lung injuries that might respond favorably to NIPPV. In a retrospective survey of 46 trauma patients with respiratory insufficiency that had been treated with NIPPV, Beltrame and coworkers found rapid improvements in gas exchange and a 72% success rate; however, patients with burns responded poorly.³⁹ More recently, a randomized trial of NIPPV versus high-flow oxygen in thoracic trauma patients with $\text{PaO}_2/\text{FiO}_2$ less than 200 was stopped early after the enrollment of 50 patients because of significant reductions in the intubation rate (12% versus 40%) and hospital length of stay (14 versus 21 days) in the NIPPV group.⁴⁰ These promising results justified a cautious trial of NIPPV in carefully selected and monitored thoracic trauma patients, but the data are too limited to draw firm conclusions.

Restrictive Lung Disease

The use of noninvasive ventilation in patients with underlying restrictive disease and acute deterioration of respiratory status has not been studied extensively because they constitute only a small portion of patients admitted to acute care hospitals. Patients with restrictions related to an underlying neuromuscular disease and superimposed acute respiratory failure may benefit from a trial of NIPPV. Small case series have reported that using NIPPV in patients with myasthenic crises may avoid intubation.^{41,42}

Patients with end-stage pulmonary fibrosis in respiratory extremis have been reported to respond poorly to mechanical ventilation.⁴³ However, in selected patients with interstitial lung diseases, NIV may play a role in preventing intubation and improving survival. A prospective observational study revealed that patients with Apache II scores < 20 and mixed interstitial lung disease requiring noncontinuous NIV had a higher survival rate than those requiring continuous NIV or invasive ventilation.⁴⁴ Similarly, a small retrospective observational study in patients with acute respiratory failure secondary to idiopathic

pulmonary fibrosis showed a poor overall prognosis, but, for those who survived, NIV helped to shorten the ICU stay and improve the 90-day survival rate.⁴⁵ Interestingly, this study also found that patients with an IPF and higher NT-proBNP at baseline appeared to have a higher chance of NIV failure.

Do-Not-Intubate Patients

Although controversial, noninvasive ventilation may be a useful tool in patients with acute respiratory failure who do not wish to be intubated. There are several reports of good outcomes (>50% survival to discharge) with noninvasive ventilation in this subset of patients, especially those with COPD and congestive heart failure.⁴⁶ Noninvasive ventilation may also be used as a palliative technique to reduce dyspnea, preserve patient autonomy, and provide time for the finalization of affairs for some terminal patients.⁴⁷ However, there is concern that this may merely prolong the dying process, and patients and their families must be informed that noninvasive ventilation is being used as a form of life support in this setting and should be given the option to refuse it.

Facilitation of Weaning and Extubation

Patients who require invasive mechanical ventilation initially and fail to wean promptly are potential candidates for noninvasive ventilation to facilitate extubation, thus reducing the complications related to prolonged intubation. Several randomized controlled trials and subsequent meta-analyses have demonstrated that noninvasive ventilation significantly shortens the duration of invasive mechanical ventilation, reduces the length of ICU stay, and improves survival compared with patients weaned in the routine fashion.⁴⁸⁻⁵⁰ The benefit of NIV in ventilator weaning seems to be highest in patients intubated for acute exacerbations of COPD.^{51,52}

Another potential application of noninvasive ventilation in the weaning process is to avoid reintubation in patients with extubation failure, a complication of invasive mechanical ventilation associated with a high mortality rate. Data for this use of NIPPV are variable and inconclusive. Earlier studies investigating the role of NIPPV in this situation showed promise, but one randomized trial found that NIPPV may delay required intubation in this setting, resulting in an increased ICU mortality rate.⁵³ More recent studies have demonstrated that patients at a high risk for extubation failure,⁵⁴ especially those with hypercapnia,⁵⁵ have a reduced need for reintubation and mortality if treated with noninvasive ventilation as opposed to oxygen supplementation alone. Subsequent meta-analyses have demonstrated that NIV, used prophylactically after planned extubation, has decreased reintubation rates.^{56,57} However, its effect on ICU and hospital mortality remains unclear. Thus, although the use of noninvasive ventilation to facilitate weaning and extubation appears to benefit hypercapnic patients with COPD or congestive heart failure, its overzealous application could lead to delayed reintubation and other adverse consequences.

Bronchoscopy

Both CPAP and NIPPV have been studied as methods of supporting oxygenation and ventilation during bronchoscopy. Using a specially designed open CPAP system during bronchoscopy in patients with marginal oxygenation, Maitre et al. observed the maintenance of adequate gas exchange and avoidance of respiratory failure.⁵⁸ In a controlled trial, Antonelli et al. demonstrated equivalent oxygenation and complication rates in patients undergoing bronchoscopy and supported with either noninvasive or invasive mechanical ventilation.⁵⁹ Thus, NIPPV is an effective way of providing ventilatory support to patients undergoing bronchoscopy.⁵⁹

PRACTICAL APPLICATION

Patient Selection

Noninvasive ventilation should be viewed as a “crutch” that assists patients through a period of acute respiratory failure while reversible

BOX 62-2**Predictors of Noninvasive Ventilation Success in Patients with Acute Respiratory Failure**

Lower acuity of illness (Acute Physiology and Chronic Health Evaluation [APACHE] score)
 Ability to cooperate; better neurologic score
 Ability to coordinate breathing with ventilator
 Less air leakage; intact dentition
 Hypercarbia, but not too severe (PaCO_2 between 45 and 92 mm Hg)
 Acidemia but not too severe (pH between 7.1 and 7.35)
 Improvements in gas exchange and heart and respiratory rates within first 2 hours

factors are being treated, helping them avoid invasive mechanical ventilation and its attendant complications. To optimize the chance of success, noninvasive ventilation should be used early, when patients first develop signs of incipient respiratory failure. In addition, predictors of success are useful in identifying patients most likely to benefit (Box 62-2). The selection process might be viewed as taking advantage of a “window of opportunity”: the window opens when the patient first requires ventilatory assistance and closes when the patient becomes too unstable.

Based on the predictors of success and criteria used in prior controlled trials, we recommend the following three-step selection process: (1) to ensure that the patient has an etiology of respiratory failure likely to respond favorably to noninvasive ventilation; (2) to identify patients in need of ventilatory assistance by using clinical and blood gas criteria. Patients with mild respiratory distress and only those with mild gas exchange derangement are likely to do well without ventilatory assistance and should not be considered. Good candidates are those with moderate to severe dyspnea, tachypnea, and impending respiratory muscle fatigue, as indicated by the use of accessory muscles of breathing or abdominal paradox. The level of tachypnea used as a criterion depends on the underlying diagnosis. Those with COPD are considered candidates for noninvasive ventilation when the respiratory rate exceeds 24 breaths per minute; with hypoxemic respiratory failure, higher respiratory rates are used in the range of 30 to 35 breaths per minute; and (3) to exclude patients for whom noninvasive ventilation would be unsafe. Those with obvious or imminent respiratory arrest should be promptly intubated because the successful initiation of noninvasive ventilation requires some time for adaptation. Patients who are medically unstable with hypotensive shock, uncontrolled upper gastrointestinal bleeding, unstable arrhythmias, or life-threatening ischemia are better managed with invasive mechanical ventilation. Additionally, noninvasive ventilation should not be used for patients who are uncooperative, unable adequately to protect their upper airway or clear secretions, intolerant of masks, or for recipients of recent upper gastrointestinal or airway surgery.

Initiation of Noninvasive Ventilation

Once an appropriate candidate for noninvasive ventilation has been selected, a ventilator and interface must be chosen, initial settings must be selected, and the patient must be monitored closely in an appropriate location until stabilized. The roles of physicians, respiratory therapists, and nurses are of paramount importance in explaining the process to and gaining the confidence of the patient. Noninvasive ventilation can be initiated wherever the patient presents with acute respiratory distress, but he or she should be transferred to a location with sufficient monitoring (usually an ICU or step-down unit) until stabilized. During transfers, ventilatory assistance and monitoring should be continued.

Ventilator Selection

Selection of a ventilator is based largely on availability, practitioner experience, and patient comfort. Pressure-limited modes, including pressure support and pressure control, are available on most critical care ventilators. Pressure control ventilation (PSV) delivers time-cycled, preset inspiratory and expiratory pressures with adjustable inspiratory/expiratory ratios at a controlled rate. The majority of such models also permit patient triggering and the selection of a backup rate. PSV delivers preset inspiratory and expiratory pressures to assist spontaneous breathing efforts. Nomenclature and the specific characteristics of these modes may differ among ventilators, and this must be taken into account to avoid errors. For example, with some ventilators, pressure support is the amount of inspiratory assistance added to the preset expiratory pressure. Others require the independent selection of inspiratory and expiratory positive airway pressures, with the difference between the two determining the level of pressure support.

PSV is a flow-triggered and flow-cycled mode, and patient effort determines tidal volume and duration of inspiration. Pressure-support modes have the potential to match breathing pattern quite closely, and they have been rated by patients as more comfortable for NIPPV than volume-limited ventilation.⁶⁰ However, leaks during noninvasive ventilation can interfere with the detection of reduced inspiratory flow at the termination of inspiration, causing expiratory asynchrony. Noninvasive pressure-limited modes of ventilation are usually administered using either standard critical care ventilators or bilevel portable ventilators.

Traditional bilevel devices designed for home use have limited pressure-generating capability (≤ 30 cm H_2O) and lack oxygen blenders or sophisticated alarm or battery backup systems, precluding their use in patients who require high oxygen concentrations or inflation pressures. Newer versions designed for the acute setting are equipped with sophisticated alarm and monitoring capabilities, graphic displays, and oxygen blenders. These devices are capable of enhancing synchrony by offering ways to limit the inspiratory duration and an adjustable “rise time”—the time to reach the targeted inspiratory pressure. Many critical care ventilators now include an “NIV” mode that enhances leak compensation capabilities and silences “nuisance” alarms; however, these may have difficulty maintaining performance in the face of variable air leaks.⁶¹ If desired, volume-limited ventilation can be delivered using critical care ventilators, but a higher tidal volume than that commonly used for invasive mechanical ventilation is recommended to compensate for air leakage.

Initial ventilator pressure settings are usually low to facilitate patient acceptance, but they can be set higher if necessary to alleviate respiratory distress. Typical starting pressures are an inspiratory positive airway pressure of 10 to 12 cm H_2O and a PEEP (or expiratory positive airway pressure) of 4 to 5 cm H_2O . L’Her et al.⁶² demonstrated that increases in inspiratory pressure are helpful to alleviate dyspnea, whereas increases in expiratory pressure are preferable to improve oxygenation. For volume ventilation, initial tidal volumes range from 6 to 7 mL/kg. The ventilator is set in a spontaneously triggered mode, with or without a backup rate. Pressures commonly used to deliver CPAP in patients with acute respiratory distress range from 5 to 12.5 cm H_2O . CPAP can be applied using compressed air with a regulator system, blower-based CPAP devices, bilevel devices, or critical care ventilators.

Interfaces

The major difference between invasive and noninvasive ventilation is that with the latter, pressurized gas is delivered to the airway via a mask rather than via an invasive conduit. The open breathing circuit of noninvasive ventilation permits air leaks around the mask or through the mouth, rendering the success of noninvasive ventilation dependent on ventilators designed to deal effectively with air leaks and to optimize patient comfort and acceptance. Interfaces, the devices that connect the ventilator tubing to the nose, mouth, or both, enable pressurized

FIGURE 62-3 ■ Full facemask with soft silicon seal to minimize pressure on the nasal bridge. A disposable version of this mask is widely used in the acute care setting.

gas to enter the upper airway during noninvasive ventilation. Commonly used interfaces in the acute setting include nasal and full-face (or oronasal) masks.

Nasal masks are widely used for the administration of CPAP or NIPPV, particularly for chronic applications. Nasal masks are usually better tolerated than full-face masks for long-term applications because they cause less claustrophobia, increased comfort, and allow eating, conversation, and expectoration. The standard nasal mask is a triangular or cone-shaped clear plastic device that fits over the nose and uses a soft cuff that forms an air seal over the skin. The mask exerts pressure over the nasal bridge, often causing skin irritation and redness, and occasionally ulceration. Many modifications are available to avoid complications, such as the use of forehead spacers or masks with ultra-thin silicon seals or heat-sensitive gels that minimize skin trauma.

Full-face masks cover both the nose and the mouth (Fig. 62-3) and are preferable to nasal masks in the acute setting. The efficacy of both nasal and oronasal masks in lowering PaCO_2 and avoiding intubation is similar in the acute setting, but a randomized controlled trial⁶³ observed better patient tolerance with full-face masks because of reduced air leakage through the mouth. More recently, “total” face masks have become available; they seal around the perimeter of the face and resemble a hockey goalie’s mask or a snorkel mask. Made of optical-grade plastic, they are easy to apply and cause no more claustrophobia than standard face masks.⁵ Mouthpieces are seldom used to administer noninvasive ventilation in the acute setting but are occasionally used during initiation when the patient holds the mouthpiece in place to adapt to the sensation of positive-pressure ventilation. Helmets are clear plastic bucket-shaped devices that fit over the entire head and seal over the shoulders and neck.⁶⁴ These have achieved popularity in some European countries but are not available for NIV in the United States.

Selection of a comfortable mask that fits properly is the key to the success of noninvasive ventilation. The full-face mask should be tried first in the acute setting, and if possible, the patient should be allowed to hold the mask in place initially. The mask straps are then tightened with the least amount of tension necessary to avoid excessive air leakage. Some leakage is acceptable and even obligatory with bilevel ventilators, because of the need to flush carbon dioxide from the single-channel ventilator circuit. However, excessive air leakage can lead to noninvasive ventilation failure with any ventilator.

BOX 62-3

Monitoring of Patients Receiving Noninvasive Ventilation in Acute Care Settings

LOCATION

Critical care or step-down unit
Medical or surgical ward if able to breathe unassisted for >20-30 min

“EYEBALL” TEST

Dyspnea
Comfort (mask, air pressure)
Anxiety
Asynchrony
Leaks

VITAL SIGNS

Respiratory and heart rates
Blood pressure
Continuous electrocardiography

GAS EXCHANGE

Continuous oximetry
Arterial blood gasses (baseline, after 1-2 h, and as clinically indicated)

Head straps hold the mask in place and are important for patient comfort. Straps attach at two to five points, depending on the type of mask. More points of attachment add to stability.

Oxygenation and Humidification

Oxygen is titrated to achieve the desired oxygen saturation, usually greater than 90% to 92%, either by using oxygen blenders in critical care and some bilevel ventilators or by adjusting the liter flow (up to 15 L/min) delivered via oxygen tubing connected directly to the mask or ventilator circuit. Bilevel ventilators have limited oxygenation capabilities (maximal inspired oxygen fraction, 0.45-0.5), so ventilators with oxygen blenders should be used for patients with hypoxemic respiratory failure. A heated humidifier should be used to prevent drying of the nasal passage and oropharynx when the duration of application is anticipated to be more than a few hours.

Monitoring

Once noninvasive ventilation is initiated, patients should be closely monitored in a critical care or step-down unit until they are sufficiently stable to be moved to a regular medical floor. The aim of monitoring is to determine whether the main goals are being achieved, including the relief of symptoms, reduced work of breathing, improved or stable gas exchange, good patient-ventilator synchrony, and patient comfort (Box 62-3). A drop in the respiratory rate with improved oxygen saturation or improving pH with a lower PaCO_2 within the first 1 to 2 hours indicates a successful outcome.⁶⁵ Abdominal paradox, if present initially, subsides, and the heart rate usually falls. The absence of these propitious signs indicates a poor response to noninvasive ventilation and the need to make further adjustments. Leaks should be sought and corrected, patient-ventilator synchrony should be optimized, and pressures may need to be adjusted upward to relieve respiratory distress and achieve a reduction in PaCO_2 . If these adjustments fail to improve the response within a few hours, noninvasive ventilation should be considered a failure, and the patient should be promptly intubated if it is still clinically indicated. Excessive delay in intubation may precipitate a respiratory crisis and add to the morbidity and mortality.

ADVERSE EFFECTS AND COMPLICATIONS

When applied by experienced caregivers to appropriately selected patients, noninvasive ventilation is usually well tolerated and is

associated with minimal complications. The most frequent adverse effects and complications are related to the mask, ventilator airflow or pressure, patient-ventilator interaction, or airway secretions.

Common adverse effects related to the mask include discomfort and erythema or skin ulcers, usually on the nasal bridge, related to pressure from the mask seal. Proper fitting and attachment, consistent use of artificial skin over the nose, and newer masks with softer silicone seals help minimize these problems. Adverse effects related to airflow or pressure include conjunctival irritation caused by air leakage under the mask into the eyes and sinus or ear pain related to excessive pressure. Refitting the mask or lowering the inspiratory pressure may ameliorate these problems. Nasal or oral dryness caused by high airflow is usually indicative of air leaking through the mouth. Measures to minimize leakage may be useful, but nasal saline or emollients and heated humidifiers are often necessary to relieve these complaints. Nasal congestion and discharge are also frequent complaints and can be treated with topical decongestants or steroids and oral antihistamine-decongestant combinations. Gastric insufflation occurs commonly, may respond to simethicone, and is usually tolerated.

Patient-ventilator asynchrony is a common occurrence during NIPPV. Failure to adequately synchronize compromises the ventilator's ability to reduce the work of breathing and may contribute to NIPPV failure. The asynchrony may be related to patient agitation, which can be treated with the judicious use of sedatives. Failure to synchronize can also result from inadequate ventilator triggering or the inability to sense the onset of patient expiration because of air leakage. This can be corrected by minimizing air leaks and using ventilator modes that permit a limitation of maximal inspiratory duration. Even with the best efforts to optimize settings and comfort, a minority of patients still fail. This may be partly due to the progression of the underlying disease process or the patient's inability to tolerate NIPPV, but every effort should be made to ascertain that it is not due to technologic problems that could be corrected by mask or ventilator adjustments. Therefore, intubation should not be delayed if improvement is not apparent within a few hours.

KEY POINTS

1. The use of noninvasive positive-pressure ventilation (NIPPV) in patients with certain forms of acute respiratory failure is becoming established, mainly because of increasing evidence for efficacy and advances in noninvasive interfaces and ventilators.
2. NIPPV delivered by nasal or oronasal mask reduces the need for endotracheal intubation, decreases the length of stay in the ICU and hospital, and reduces mortality when used in selected patients with exacerbations of chronic obstructive pulmonary disease (COPD).
3. The efficacy of NIPPV has been demonstrated for acute pulmonary edema, for mild to moderate respiratory failure in immunocompromised patients, and to facilitate extubation in COPD patients.
4. Patients who develop respiratory failure and who refuse intubation are potentially good candidates for NIPPV, but all patients must be selected carefully.
5. Several factors are vital to the success of NIPPV: careful patient selection; properly timed initiation; comfortable, well-fitting interface; coaching and encouragement; and careful monitoring.
6. Noninvasive ventilation should be used to avert endotracheal intubation rather than as an alternative to it. One should not persist in the use of NIPPV if it leads to a delay in necessary intubation.
7. A trial of noninvasive ventilation should be instituted in properly selected patients with acute respiratory failure before a respiratory arrest is imminent, to provide ventilatory assistance while the factors responsible for the respiratory failure are aggressively treated.
8. Noninvasive ventilation is an important addition to the methods available to assist patients with acute respiratory failure and, if properly applied, improves patient outcome in the critical care setting.

THE CONCEPT OF LIBERATION AND EXTUBATION

Weaning from mechanical ventilation represents the period of transition from total ventilatory support to spontaneous breathing. About 70% of intubated mechanically ventilated patients are extubated on the first spontaneous breathing trial (SBT) attempt, whether by disconnection from the ventilator or after breathing at low levels of pressure support for short periods of time, such as 30 to 120 minutes.^{1,2} The remaining patients (about 30%) require progressive withdrawal from artificial ventilatory support.

Early liberation from mechanical ventilation and removal of the endotracheal tube is clinically important. Unnecessary prolongation of mechanical ventilation increases the risks of complications, including infections (particularly of bronchopulmonary origin), barotrauma, cardiovascular compromise, tracheal injuries, and muscle deconditioning. Clinicians should hasten the process that ultimately leads to removal of the endotracheal tube to maximize patient outcome.³

Liberation and extubation are different issues.⁴ Liberation refers to weaning from mechanical ventilation and means that a patient no longer requires ventilatory support. When this step is achieved, the clinician has to consider a different question, i.e.: "Is the patient able to breathe spontaneously without the endotracheal tube?" Removal of the endotracheal tube is referred to as extubation. Regarding magnitude, the extubation failure rate (i.e., the need to replace the endotracheal tube and reinstitute mechanical ventilation) is variable and ranges from 5% to 20% of extubated patients.^{1,5-7}

MECHANISMS EXPLAINING LIBERATION FAILURE

Respiratory Pump Failure

The most common reason for weaning failure is respiratory pump insufficiency and is caused by an imbalance between the patient's capabilities and respiratory demands.⁸⁻¹¹ Jubran and Tobin¹² investigated the progression of respiratory mechanics during SBT in patients with chronic obstructive pulmonary disease (COPD). At the very beginning of the trials, patients who subsequently failed had a slightly higher airway resistance, respiratory system elastance, and intrinsic positive end-expiratory pressure (PEEP) compared to those who succeeded. However, during the trials, respiratory mechanics progressively worsened in patients who failed to be liberated from the ventilator. Subjects who failed developed rapid, shallow breathing and most developed an increase in PaCO₂. Together, these abnormalities resulted in increased inspiratory muscle effort, which in some patients was likely close to the threshold of muscle fatigue.

Laghi et al.¹³ studied 19 intubated patients during weaning from mechanical ventilation, of which 11 patients failed and 8 succeeded. Several physiologic indices were measured before and 30 minutes after SBT. The transdiaphragmatic twitch pressure, elicited by magnetic bilateral phrenic stimulation, did not differ before the SBT between the patients that failed or succeeded at ventilator liberation, and this variable did not decrease after the trial in either group. Patients failing the SBT were reconnected to the ventilator due to clinical signs of intolerance. It was concluded that weaning failure was not accompanied

by low-frequency diaphragmatic fatigue, although weaning failure patients exhibited severe diaphragmatic weakness since twitch pressures were always low.

Common Disorders That Alter the Balance of Capacity and Load in Critical Illness

Reduced Neuromuscular Capacity. Previous studies have shown that diaphragmatic injury and atrophy are associated with the use of passive assisted control ventilation^{14,15} and are significantly correlated with longer periods of ventilator support.¹⁶ Critical illness polyneuropathy and myopathy, which are frequent complications of sepsis and multiple organ system failures, may also impede weaning.¹⁷ In addition, respiratory muscle weakness is associated with delayed extubation.¹⁸ Finally, malnutrition and deconditioning due to prolonged bed rest during critical illness can induce severe muscle dysfunction.¹⁹

Increased Muscle Loads. The increased work of breathing results from increased mechanical loads (elastic and/or resistive). Increased elastic workloads occur when lung and chest wall compliance are reduced (e.g., pulmonary edema, extreme hyperinflation during an acute asthmatic attack, pulmonary fibrosis, abdominal distension, obesity, trauma, or thoracic deformities).¹³ The presence of intrinsic PEEP is another example of increased elastic workload and is a relatively common phenomenon, especially in patients with COPD.^{20,21} Resistive work for breathing during critical illness may increase as a result of bronchospasm, excessive secretions, endotracheal tube resistance (which augments with kinking and deposition of secretions), and ventilator valves/circuits and humidifiers, especially when conditioning of inspired gases is provided with heat and moisture exchangers. The latter also increases the instrumental dead space.

Cardiovascular Dysfunction

The presence of cardiovascular dysfunction can contribute to weaning failure by augmenting the loads on the respiratory system and by reducing neuromuscular capacity.^{22,23} Cardiovascular dysfunction can result from physiologic changes that occur during the resumption of unassisted spontaneous breathing.²⁴ When spontaneous breathing resumes, the intrathoracic pressure during inspiration is negative. This becomes a situation that results in increased left ventricular preload and afterload. Increased heart loads augment myocardial oxygen demand and may precipitate myocardial ischemia in patients with coronary artery disease.²⁵

Jubran et al.²⁶ examined hemodynamics and mixed venous saturations in patients during weaning trials. Successfully weaned patients demonstrated increases in cardiac index and oxygen transport compared to values during mechanical ventilation. Patients who failed weaning did not increase oxygen delivery to the tissues due in part to the elevated right and left ventricular afterloads. Consequently, these abnormalities can jeopardize respiratory muscle function.

In intensive care unit (ICU) patients, congestive heart failure may occur as a consequence of an increase in venous return, volume overload, or catecholamine release induced by physiologic stress, such as weaning.^{24,27,28} Impairment of cardiovascular function can be magnified in the setting of a positive fluid balance.^{29,30}

It has been recently shown that performing an SBT using a T-tube (instead of pressure support and PEEP) is difficult to wean patients elicits a different cardiovascular response and when support is added

(in the form of pressure support and PEEP), respiratory and cardiovascular function both improve.³¹

In the ICU, there are noninvasive tools (e.g., echocardiography and measurement of plasma B-type natriuretic peptide [BNP]) that help to make the diagnosis of cardiovascular dysfunction. Mekontso-Desap et al.³² measured BNP levels during weaning trials. In this study, 41% of patients failed the weaning process and high BNP levels were identified as an independent risk factor for weaning failure. In addition, 9 of the 42 patients in whom weaning failed were successfully weaned after the administration of diuretics.

PREDICTION OF WEANING AND EXTUBATION OUTCOMES

Yang and Tobin³³ studied the predictive power of several weaning indices and showed that the rapid shallow breathing index (f/VT) had the best predictive value. In their study, 95% of patients with a ratio f/VT greater than 105 failed during a test of spontaneous breathing. The rapid shallow breathing index appears to be the most useful method at the bedside to screen a patient for liberation readiness. If the value is less than 105, then 30-120 minutes of an SBT should be used as a confirmation of the capability of breathing spontaneously without assistance. However, since the f/VT has a low specificity (there is a relatively large proportion of weaning failure subjects in whom the test is positive), the f/VT alone is not sufficient to predict weaning failure. From a practical point of view, the information conveyed by weaning indices and clinical judgment should be considered together in making clinically important decisions regarding extubation.

Patients incapable of protecting their airway and clearing secretions with an effective cough are at an increased risk of extubation failure. Traditional assessment has consisted of demonstrating a cough reflex when the airways are stimulated with a suction catheter and by the absence of excessive secretions. Smina et al.³⁴ found that patients with a peak expiratory flow equal to or below 60 L/min were five times more likely to have an unsuccessful extubation than patients with expiratory flows greater than 60 L/min.

EXTUBATION FAILURE

Extubation failure can be defined as reintubation and the reinstitution of ventilatory assistance within 24-48 hours of extubation. Data by Esteban et al.^{5,35} indicate that the reintubation rate is about 13%-19%.

Mechanisms explaining extubation failure include impending abnormalities not diagnosed at the time that extubation was performed (e.g., pneumonia or ongoing cardiac failure) and the inability to keep the tracheobronchial tree free of copious secretions.^{7,36,37} Extubation failure results in a marked increase in the duration of mechanical ventilation, ICU and hospital stay, need for tracheostomy, and hospital mortality.^{5,7,38-40} Further studies are needed to understand the pathophysiological mechanisms of extubation failure.

PROGRESSIVE WITHDRAWAL OF MECHANICAL VENTILATION

When patients fail SBTs, pressure support ventilation (PSV) is the modality most often used for the progressive withdrawal of mechanical ventilation.⁴¹ Two prospective multicenter randomized clinical trials have shown that the use of synchronized intermittent mandatory ventilation (SIMV) is less efficacious than other techniques.^{1,2}

Sedation and analgesia are important components of care for mechanically ventilated patients. An important study revealed that the daily interruption of sedation significantly reduced the duration of mechanical ventilation.⁴² Since sedation and weaning from mechanical ventilation cannot be separated from one another, when these two strategies are combined (i.e., daily interruption of sedation and the systematic use of SBTs) to hasten liberation from the ventilator, the results are more effective than if the two strategies are used separately.⁴³

PSV

Clinical experience^{1,2} and data obtained from clinical trials^{44,45} suggest that the "optimal" initial levels for PSV are those that provide respiratory rates between 25 and 30 breaths/min. In this setting, it is particularly important to rule out the existence of asynchronous breathing or ineffective respiratory effort. A ventilator setting with a high level of pressure support can be the cause of patient-ventilator asynchrony. The patients who show ineffective triggering exhibit a longer time on mechanical ventilation and tracheostomy is more frequent in these patients.⁴⁶ A subsequent study found a decrease in the number of ineffective respiratory efforts without changes in the work required for breathing and without modifications in the respiratory rate when pressure support levels were reduced.⁴⁷ These studies^{46,47} indicate that some patients are receiving excessive levels of mechanical ventilation during the weaning process.

The level of external PEEP used in patients with clinically suspected dynamic hyperinflation and dynamic airway collapse should be adjusted with great caution since the measurement of dynamic intrinsic PEEP in spontaneously breathing patients is not easily performed. To that end, it has been suggested that external PEEP can be titrated according to the changes in airway occlusion pressure.⁴⁸

During weaning, the PSV levels are decreased according to the patient's clinical tolerance, usually by steps of 2-4 cm H₂O at least twice a day. In general, clinical tolerance to a level of PSV of about 8 cm H₂O without PEEP is required before performing extubation, although this level may vary according to a given patient's overall clinical status.

Spontaneous Breathing with T-Tube

Tolerance to breathing through a T-tube represents a good test to evaluate patients' capacity to maintain autonomous, spontaneous breathing.⁴⁹ The optimal duration of a T-tube trial is at least 30 minutes and no more than 120 minutes.

The main disadvantage of the T-tube trial is related to the absence of a connection to a mechanical ventilator. Since the patients are not monitored by the alarms on the ventilator, they need to be closely supervised.

SBTs with pressure support or a T-tube are suitable methods for evaluating the capacity for spontaneous breathing.⁵ However, the use of T-tube weaning trials in difficult-to-wean patients should be considered since PSV modifies the breathing pattern, inspiratory muscle effort, and cardiovascular response compared to the T-tube in this group of patients.³¹

Noninvasive Ventilation

Noninvasive ventilation (NIV) could be used in some clinical scenarios during weaning:

1. Preventive NIV in patients considered high-risk candidates for reintubation.⁵⁰ Examples of such patients include those who have hypercapnia at the end of the weaning test and patients with a history of heart problems or chronic hypercapnic respiratory failure.⁵¹⁻⁵³ One study demonstrated a reduction in the reintubation rate when NIV was used postextubation.⁵¹ Another study showed both a reduction in reintubation and mortality rates with the use of NIV.⁵² Finally, the study of Girault et al.⁵³ found that NIV could improve weaning results in chronic hypercapnic respiratory failure patients by shortening the duration of intubation and reducing the risk of postextubation acute respiratory failure. However, no differences in reintubation and mortality rates were found.
2. NIV for respiratory failure after extubation. A Canadian study examined the use of NIV for respiratory failure after extubation but found no difference regarding reintubation or mortality.⁵⁴ In 2004, a study was published questioning the use of NIV for postextubation respiratory failure.⁵⁵ The patients were randomized to receive treatment with oxygen and usual care versus NIV treatment and intubation if needed. Although the rate of reintubation was similar

to the Canadian study, the group treated initially with NIV had a higher mortality rate. These results have ended the indiscriminate use of NIV so that NIV is only recommended for specific populations, including those with chronic respiratory problems⁵⁶ and selected postoperative patients.^{57,58}

The high-flow nasal cannula (HFNC) is a relatively new system that delivers heated and humidified oxygen via nasal prongs with a maximum flow of 60 L/min. HFNC provides a low level of positive airway pressure (<4 cm H₂O), which is highly dependent on mouth closing.⁵⁹ Several studies have found that HFNC can be used in weaning period. Maggiore et al.⁶⁰ conducted a randomized trial on 105 patients with a PaO₂/FiO₂ ratio < 300 mm Hg immediately before they were extubated. A total of 52 patients were conventionally treated with Venturi mask, and 53 patients were treated with HFNC during the initial 48 hours after extubation. The HFNC group as compared to those patients randomized to a Venturi mask resulted in significantly better oxygenation, significantly less discomfort associated with the respiratory device, and a significantly lower reintubation rate. Adequately powered randomized studies are needed to confirm or refute the hypothesis for the benefits associated with HFNC.

New Modalities

Several novel weaning modalities have been examined, including those using closed-loop PSV^{61,62} and that provide a continuous adaptation of ventilator assistance to the patient's needs 24 hours a day.⁶³ Lellouche et al. examined this modality in two groups of patients during the weaning period.⁶⁴ In the control group, weaning was performed as per usual care based on written weaning guidelines. In the study group, weaning was performed using a computer-driven weaning protocol. In the study group, weaning time was significantly reduced in comparison to usual weaning (3 days vs. 5 days; $P = 0.01$). The reduction in the weaning time was associated with a decrease in both the total duration of mechanical ventilation (7.5 days vs. 12 days; $P = 0.003$) and the ICU length of stay (12 days vs. 15.5 days; $P = 0.02$).

A subsequent study by Rose et al.,⁶⁵ comparing weaning duration with a closed-loop mode versus usual care (weaning managed by experienced critical care specialty nurses using a 1:1 nurse-to-patient ratio) found no differences between the two strategies. Schadler et al.⁶⁶ found

that the closed-loop system decreased the duration of mechanical ventilation in a specific subgroup of patients (cardiac surgery). Finally, a study by Burns et al.⁶⁷ compared automated weaning with closed-loop mode versus a standardized protocol in critically ill patients and found that automated weaning patients had significantly shorter median times to first successful SBT (1 day vs. 4 days; $P < 0.001$) and to successful extubation (4 days vs. 5 days; $P = 0.01$).

CLASSIFICATION OF WEANING

A Consensus Conference classification⁶⁸ defined 3 groups of patients who were weaned: (1) simple weaning (i.e., those patients who proceed from initiation of weaning to successful extubation on the first attempt); (2) difficult weaning (i.e., those patients who fail initial weaning and require up to 7 days from the first SBT to achieve successful weaning); and (3) prolonged weaning (i.e., those patients who require more than 7 days from the first SBT to achieve successful weaning).

The objective of this classification was to provide greater epidemiologic insight in the weaning process and its relationship with outcomes.⁶⁸ The simple weaning group represents 60%-70% of ventilated patients, the difficult group includes 20%-25% of patients, and the prolonged group includes the remaining 5%-15% of patients.⁶⁹ Several studies⁷⁰⁻⁷⁴ have evaluated this classification and the distribution among groups is shown in Fig. 63-1, outcomes are shown in Table 63-1, and an overall summary of results shown in Fig. 63-2. These data confirm that simple weaning is the most common scenario and that prolonged weaning is associated with poorer outcomes.

SUMMARY

The vast majority of intubated mechanically ventilated patients can be successfully liberated from the ventilator after passing an SBT. The best strategy to shorten the total time of mechanical ventilation is based on a simple and daily clinical approach that determines the ability of patients to tolerate unassisted spontaneous breathing. This approach requires that a screening test is performed as early as possible each day and if positive, the patient is continued a confirmatory SBT of 30 to 120 minutes of duration. When patients fail SBTs, techniques for progressive withdrawal of mechanical ventilation can be used. PSV is the

FIGURE 63-1 ■ Patient's distribution in different studies according to the Conference classification.

TABLE 63-1 Outcomes of the Different Studies According to the Conference Classification

| VARIABLE | STUDY | SIMPLE WEANING | DIFFICULT WEANING | PROLONGED WEANING |
|-------------------|--------------------------------|----------------|-------------------|-------------------|
| Reintubation | Funk et al. (n = 257) | 13% | 7% | 5% |
| | Sellares et al. (n = 181) | 15% | 19% | 33% |
| | Peñuelas et al. (n = 2714) | 10% | 10% | 16% |
| | Tonnelier et al. (n = 115) | 0% | 6% | 15% |
| | Aguirre-Bermeo et al. (n = 95) | 7% | 19% | 73% |
| Tracheotomy | Funk et al. (n = 257) | 7% | 15% | 68% |
| | Sellares et al. (n = 181) | 8% | 9% | 39% |
| | Peñuelas et al. (n = 2714) | 6% | 6% | 10% |
| | Aguirre-Bermeo et al. (n = 95) | 3% | 10% | 50% |
| ICU stay, (days)* | Funk et al. (n = 257) | 4 (1-9) | 11 (7-20) | 27 (18-37) |
| | Sellares et al. (n = 181) | 11 ± 12 | 12 ± 8 | 21 ± 13 |
| | Peñuelas et al. (n = 2714) | 6 (3-10) | 9 (6-15) | 18 (14-25) |
| | Tonnelier et al. (n = 115) | 10 ± 9 | 16 ± 15 | 30 ± 25 |
| | Aguirre-Bermeo et al. (n = 95) | 10 ± 7 | 17 ± 13 | 24 ± 15 |
| ICU mortality | Funk et al. (n = 257) | 3% | 1% | 22% |
| | Sellares et al. (n = 181) | 13% | 11% | 42% |
| | Peñuelas et al. (n = 2714) | 7% | 7% | 13% |
| | Tonnelier et al. (n = 115) | 0% | 2% | 18% |
| | Aguirre-Bermeo et al. (n = 95) | 3% | 5% | 38% |

modality most often used in this scenario. Automated systems seem to perform at least as well as usual care and perhaps even better. NIV may be useful to hasten the weaning process and avoid reintubation in selected populations. Patients with a long weaning duration (>7 days from the first SBT) have poorer outcomes. Extubation failure is poorly understood and is associated with a high mortality rate.

KEY POINTS

1. In the vast majority of patients, weaning from mechanical ventilation is a simple process. Patients are extubated at the first SBT attempt. This is associated with favorable outcomes.
2. The implementation of a weaning strategy based on solid clinical and pathophysiologic knowledge improves outcomes regarding the duration of mechanical ventilation and length of stay in the ICU. This effect can be attributed primarily to the fact that patients are screened daily for the capability to maintain spontaneous breathing.
3. A relatively small group of patients require prolonged weaning. This is associated with worsened outcomes. These patients need to be carefully evaluated for neuromuscular and cardiovascular dysfunction and could benefit from adjunctive therapy.
4. Mechanisms explaining extubation failure are still poorly understood and much research is needed in this area. Patients with extubation failure have an increased mortality rate that varies depending on the specific cause of the failure.
5. Noninvasive ventilation is used to facilitate weaning and extubation but with some reservations. Patients should be carefully selected and the NIV administration should be tailored in a patient per patient basis.

ANNOTATED REFERENCES

Brochard L, Rauss A, Benito S, et al. Comparison of three methods of gradual withdrawal from ventilatory support during weaning from mechanical ventilation. *Am J Respir Crit Care Med* 1994;150(4):896-903.

This is the first randomized trial comparing three different methods of weaning. They conclude that the outcome of weaning is influenced by the modality chosen during this period. The weaning duration was shorter with pressure support compared with SIMV or T-tube when pooled together.

Esteban A, Frutos F, Tobin MJ, et al. A comparison of four methods of weaning patients from mechanical ventilation. Spanish Lung Failure Collaborative Group. *N Engl J Med* 1995;332(6):345-50.

This is a randomized multicenter study comparing four different methods of weaning. They show that a once daily spontaneous breathing trial is twice as fast as pressure support and three times more rapid than SIMV. Multiple trials of spontaneous breathing do not reduce the time of weaning compared with the once daily trial.

Girard TD, Kress JP, Fuchs BD, et al. Efficacy and safety of a paired sedation and ventilator weaning protocol for mechanically ventilated patients in intensive care (Awakening and Breathing Controlled trial): a randomised controlled trial. *Lancet* 2008;371(9607):126-34.

This study demonstrated that a strategy combining cessation of sedation followed by spontaneous breathing shortens the duration of mechanical ventilation and improves patient outcome.

Jubran A, Tobin MJ. Pathophysiologic basis of acute respiratory distress in patients who fail a trial of weaning from mechanical ventilation. *Am J Respir Crit Care Med* 1997;155(3):906-15.

This is a physiologic study to determine the mechanisms of acute respiratory distress. They show that COPD patients who failed the spontaneous breathing trial developed rapid shallow breathing with worsening pulmonary mechanics, resulting in an increased PaCO₂.

Thille AW, Richard JC, Brochard L. The decision to extubate in the intensive care unit. *Am J Respir Crit Care Med* 2013;187(12):1294-302.

This is a clinical review of extubation in the ICU with an analysis of risk factors and impact of extubation failure. This review discusses the weaning tests and the optimal strategies for weaning in patients at high risk for extubation failure.

Many critically ill patients are unable to effectively clear secretions that accumulate in the central and peripheral airways. This can be due to factors such as increased secretion production, impaired cough reflex, weakness, and pain. An endotracheal tube prevents closure of the glottis to generate high expiratory pressures necessary for an effective cough, thereby promoting the retention of secretions. In addition, in critically ill patients, cilia in the pulmonary tree are impaired in function and reduced in number.^{1,2} This leads to an increased risk of aspiration, atelectasis, and pneumonia, which are all detrimental to a critically ill patient.

Adjunctive respiratory therapies aim to prevent and treat respiratory complications that are encountered in critically ill patients (Table 64-1).

METHODS TO IMPROVE PULMONARY MUCOCILIARY CLEARANCE

Percussion

Percussion of the chest can aid in secretion clearance. By using clapping cupped hands over the thorax in a rhythmic fashion or using mechanical devices that mimic the same action, the energy of the force generated is transmitted through the thorax to dislodge any secretions. When used in conjunction with postural drainage, this is an effective method to mobilize secretions from the pulmonary tract.³

High-Frequency Chest Compression

High-frequency chest compression (HFCC) enhances mucus clearance. Using an automated vest device worn by the patient that is attached to an air-pulse generator, small volumes of gas are introduced at a rapid rate ranging from 5 to 25 Hz, producing pressures up to 50 cm H₂O. This technique, primarily used in cystic fibrosis patients, is equivalent to conventional chest physiotherapy techniques of percussion and postural drainage.^{4,5} In an observational study comparing HFCC to percussion and postural drainage in nine long-term mechanically ventilated patients, no difference was seen in the amount of sputum production, oxygen saturation, or patient comfort.⁶ HFCC was determined to be safe and felt to save staff time. In a small randomized trial of patients extubated after being ventilated for more than 21 days, the addition of HFCC improved sputum clearance but did not have a significant impact on weaning success rates.⁷ It is difficult to apply this technique to most critically ill patients because of the size of the vest, as covering the thorax may prevent adequate monitoring.

Manual Hyperinflation

Manual hyperinflation with an inflation bag aims to inflate the lungs slowly to 1.5 to 2 times the tidal volume or to peak airway pressures of 40 cm H₂O. An inspiratory pause allows for filling of alveoli with slow time constants. This is followed by a quick release to allow for rapid expiration. The goal is to recruit atelectatic lung regions to improve oxygenation and improve clearance of secretions. Similar to recruitment maneuvers described with mechanical ventilators, manual hyperinflation leads to only transient improvements in oxygenation. Thus, it may facilitate secretion clearance but without any long-term

clinically significant improvement in patient outcome.⁸⁻¹² It also has the disadvantage of requiring a ventilator disconnect and this method can be mimicked by a mechanical ventilator.¹³

Contraindications to manual hyperinflation include hemodynamic compromise and elevated intracranial pressure. There is also a risk of barotrauma due to preferential inflation of open lung regions that are highly compliant compared to the collapsed regions.

Positioning and Mobilization

Mobilization of patients in the intensive care unit (ICU) either through active or passive limb exercises may improve overall patient well-being and, in the long term, may lead to better patient outcomes. The addition of early physiotherapy and occupational therapy to daily interruption of sedation resulted in slightly more ventilator-free days and improved functional capacity.¹⁴

Positioning of the patient with the head of the bed elevated at least 30 degrees significantly reduces the risk of aspiration and ventilator-associated pneumonia.¹⁵ Upright positioning of patients in whom there is no contraindication improves lung volumes and therefore gas exchange and work of breathing, especially in those where the supine or semirecumbent position leads to increased work of breathing. In some individuals with unilateral lung disease, positioning with the affected side up can lead to improved ventilation/perfusion (\dot{V}/\dot{Q}) matching by increasing perfusion to the dependent “good” side.^{16,17} If atelectasis secondary to retained secretions is the cause, having the affected side up leads to improved postural drainage.

Postural drainage involves positioning the body to allow gravity to assist in the movement of secretions and is indicated in patients with sputum production of more than 25 to 30 mL/day and who have difficulty clearing their secretions.¹⁸

Tracheal Suction

Used in conjunction with other techniques to mobilize secretions from the peripheral to the central airways, suctioning is an effective way of removing secretions to improve bronchial hygiene. Using an open method, the patient is disconnected from the ventilator and a disposable suction catheter is inserted. A closed system involves a suction catheter placed in a protective sheath and directly connected to the ventilator circuit. No disconnect is required and the risk of environmental cross-contamination is reduced. Routine changes of the in-line suction catheters are not required and are cost-effective.^{21,22} Overall, the risk of nosocomial pneumonia between the two systems is not different.²³⁻²⁵

Due to the anatomic arrangement of the large central airways, a suction catheter most often preferentially enters the right main bronchus over the left side. Specially designed curved-tipped “left sided” suction catheters increase the likelihood of suctioning from the left mainstem bronchus.

Nasotracheal suctioning has fallen out of favor over direct tracheal suctioning and should only be considered in patients who are able to protect their airway and in conjunction with assisted coughs and other forms of chest physiotherapy.

Complications with suctioning include hypoxemia (especially in the setting of a ventilator disconnect), increased intracranial pressure,

- Prostaglandins

Helium-oxygen (heliox)

mechanical trauma to the trachea, bronchospasm, and bacterial contamination. All patients should be preoxygenated with 100% oxygen for 1 or 2 minutes prior to suctioning. To reduce the risk of agitation, the patient should be informed before tracheal suctioning is performed. The suctioning should be limited to 15 to 20 seconds, and the suction port on the catheter should be opened and closed intermittently, but not closed for more than 5 seconds at a time.

Continuous Rotation Therapy

Continuous rotational or kinetic therapy extends the practice of regular twice hourly repositioning of patients from one side to the other by placing the patient on a bed that moves to preprogrammed angles on a more frequent basis or through the use of air mattresses that deflate alternatively from side to side to provide postural position changes. Most studies demonstrate a lower incidence of nosocomial pneumonia or atelectasis.²⁶⁻³² A systematic review did not demonstrate improvements in mortality or the duration of mechanical ventilation with kinetic therapy.³³

Bronchoscopy

Fiberoptic bronchoscopy has the advantage of providing direct visualization of the airways and permits suctioning of specific segments where secretions may be retained. As a recent review highlighted,³⁴ bronchoscopy is a moderately effective technique for the treatment of atelectasis in critically ill patients, with success rates ranging from 19% to 89% depending on the extent of the atelectasis (lobar atelectasis responds better than subsegmental atelectasis). When compared with aggressive multimodal chest physiotherapy in the only randomized trial, no

difference in the rate of resolution was observed between the two methods.³⁵ Since bronchoscopy is an invasive procedure, it is not without associated risks and complications: the sedation required for the procedure, transient increases in intracranial pressure, hypoxemia, and hemodynamic consequences or arrhythmias. Therefore bronchoscopy is not recommended except in situations, such as extensive unilateral atelectasis leading to significant difficulties in oxygenating or ventilating that have not resolved with other methods (e.g., suctioning).

Chest Physiotherapy

Chest physiotherapy is a multimodal therapy with the goals of improving pulmonary function (gas exchange, improved lung compliance, and improved pulmonary mucus clearance). Techniques include percussive therapies (manual or mechanical chest percussion), postural drainage, chest vibration, manual hyperinflation, mobilization, suctioning, and rotational therapy. Overall, chest physiotherapy provides transient improvements in oxygenation and lung compliance, likely secondary to airway clearance and the recruitment of atelectatic regions. In specific situations, it may improve outcome and clinical course, such as preventing ventilator-associated pneumonia³⁶ or acute lobar atelectasis.³⁷

Aerosol Therapies**Aerosolization**

Aerosolization of medications allows direct delivery and activity at the site of pathology and the ability to deliver high concentrations with minimal systemic absorption and toxicity.

The two most common methods of delivery by aerosolization are via: 1) nebulization; or 2) metered-dose inhalers (MDIs). *Nebulization*, commonly with a pneumatic jet, uses a high flow of gas (usually 6-8 L/min) to produce small particles of the liquid medium with the medication of interest. In the spontaneously breathing patient, approximately 50% of the nebulized liquid is in the respirable range, with a mass median aerodynamic diameter (MMAD) of 1 to 5 μm . Approximately 10% reaches the lower respiratory tract and small airways. In mechanically ventilated patients, 1% to 15% of the nebulized liquid and medication is delivered to the lower respiratory tract. Ultrasonic nebulization uses high-frequency ultrasonic waves on the surface of the liquid medium to generate respirable particles.

MDIs are pressurized canisters with the drug suspended as a mix of propellants, preservatives, and surfactants. Upon activation, particles ranging in size from 1 to 2 μm are produced. An MDI used in conjunction with a chamber or spacer device significantly increases drug delivery in both spontaneously breathing patients and when attached to the ventilator circuit either directly to the endotracheal tube or as part of an in-line device in the inspiratory limb of the Y-piece.

Factors that influence the efficacy of aerosol delivery in mechanically ventilated patients include³⁸:

1. Administration position in the circuit: an MDI should be closer to the endotracheal tube at the Y-piece and used with a spacer. A pneumatic nebulizer should be at least 30 cm from the Y-piece.
2. Humidification: can decrease aerosol delivery to the respiratory tract due to greater deposition in the ventilator circuit. Higher doses may be required to achieve the desired effect.
3. Timing of delivery: delivery should occur during the inspiratory phase to maximize drug delivery.
4. Flow rates: slower inspiratory flow rates (and therefore longer inspiratory time) increase the delivery of nebulized medications. A decelerating flow pattern can also increase the delivery to the lower airways.
5. Tidal volumes: larger tidal volumes (greater than 500 mL) ensure optimal delivery.
6. Endotracheal tube size: tube sizes less than 7 mm reduce delivery.
7. Density of inhaled gas: low-density gases, such as helium-oxygen mixtures, increase deposition to the lower airways by increasing the laminar flow and producing a smaller respirable particle size.

Bronchodilators

Bronchodilators are the most frequently administered aerosolized therapy in critically ill patients. Inhaled β_2 -agonists, such as albuterol or fenoterol, are generally well tolerated in a critically ill patient and improve lung mechanics particularly in patients with reversible airflow obstruction. In acute lung injury, β_2 -agonists may improve lung edema clearance and have additional antiinflammatory properties. However, the clinical significance of such therapy has yet to be established.³⁹⁻⁴² Adverse effects (e.g., arrhythmias, hypokalemia) can occur in patients receiving excessive doses where significant systemic absorption is likely. Other bronchodilators, including ipratropium bromide, can also be effective in patients with increased airway reactivity, especially when used in conjunction with a β_2 -agonist. Bronchodilators administered via MDI are equally as effective as a nebulizer in spontaneously breathing patients.³⁸ In mechanically ventilated patients, the use of nebulization is either equally as good⁴³ or less effective^{44,45} than an MDI with a spacer. MDI administration has the advantage of easier use without the risk of bacterial contamination and the need to adjust flow rates.³⁸

Antibiotics

Theoretical advantages of aerosolized antibiotics include direct therapy to the site of infection at higher concentrations with a lower risk of systemic absorption and side effects. In chronic pulmonary infective states (e.g., cystic fibrosis and severe bronchiectasis),⁴⁶⁻⁴⁸ aerosolized antibiotics have a role in reducing bacterial concentrations in the sputum, but they have only been shown to provide clinical long-term benefits in cystic fibrosis.⁴⁸ In the acute infective state, aerosolized antibiotics have no additional benefit compared to parenteral antibiotics.⁴⁹⁻⁵¹

In the intubated or tracheostomized patient, the risk of colonization of the airway is high, with a significant increase in the risk for nosocomial pneumonia. As a preventive measure, a recent meta-analysis of prospective clinical trials of aerosolized aminoglycosides suggested a significant reduction in the development of ventilator-associated pneumonia but no difference in overall mortality.⁵² As an adjuvant for the treatment of ventilator-associated pneumonia, a recent review⁵³ and a meta-analysis of five randomized controlled trials suggested a significant improvement in the clinical resolution of pneumonia.⁵⁴ Despite these findings, limitations of these analyses must be considered, given the heterogeneity of the trials. Bacterial resistance must also be considered. Side effects reported in spontaneously breathing patients treated with inhaled tobramycin include increased cough, dyspnea, and chest pain.⁴⁶

Mucoactive Agents

In chronic inflammatory lung conditions such as chronic obstructive pulmonary disease (COPD), cystic fibrosis, bronchiectasis, and intubation/tracheostomy, the overproduction of mucus and impaired clearance results in complications such as airflow obstruction, atelectasis, and infection. Mucus is primarily composed of water, mucin glycoprotein, cellular debris, neutrophil-derived filamentous actin and DNA, and bacteria.⁵⁵

Mucolytic agents reduce the viscosity of mucus by breaking down the mucin glycoprotein network or free DNA strands, thereby improving mucus rheology to improve clearance. Aerosolized *N*-acetylcysteine (NAC) breaks down the disulfide bonds of the mucin glycoprotein network and is associated with improved mucus clearance. However, due to the increased incidence of bronchospasm with its use, therapy with NAC is not frequently initiated but may be used in conjunction with an inhaled bronchodilator.⁵⁵ Recombinant human DNase (rhDNase, dornase alpha) improves mucus viscosity and pulmonary function in the cystic fibrosis patients but has no significant effect in acute exacerbations of cystic fibrosis.^{56,57} In bronchiectasis not due to cystic fibrosis, rhDNase is not effective and may be potentially harmful.⁵⁸ In mechanically ventilated patients with atelectasis, there is no significant improvement in clinical outcome.^{59,60}

Other Aerosol Therapies

Additional aerosol therapies include hypertonic saline, racemic epinephrine (for acute upper airway obstruction due to inflammation), corticosteroids, and surfactant.

METHODS TO IMPROVE LUNG EXPANSION

Lung expansion techniques that mimic normal sigh maneuvers may help reverse and prevent atelectasis. These techniques are often used in postoperative patients at high risk for pulmonary complications, such as those undergoing thoracic and upper abdominal surgery, as well as patients with neuromuscular or chest wall disorders.

Deep breathing and incentive spirometry involve coached inspiratory maneuvers to voluntarily increase lung volumes greater than the vital capacity of the patient. Both are equally effective in reducing postoperative pulmonary complications compared to chest physiotherapy.⁶¹

A recent systematic review of continuous positive airway pressure (CPAP) in the postoperative setting for upper abdominal surgery suggested a reduction in atelectasis and the need for reintubation but no improvement in mortality or need for ICU admission.⁶²

Intermittent positive pressure breathing to improve lung expansion has fallen out of favor as a preventive measure in postoperative patients due to the expense, lack of a difference in outcomes compared to deep breathing or incentive spirometry, and complications such as abdominal distension.⁶³

METHODS TO IMPROVE OXYGENATION AND VENTILATION

Nitric Oxide

Nitric oxide (NO) is a vascular-derived relaxing factor that causes vasodilation via vascular smooth muscle relaxation. The main action of NO is mediated by activating guanylate cyclase, increasing intracellular cyclic guanylate monophosphate (cGMP), thereby causing smooth muscle and subsequent vasomotor relaxation.⁶⁴ The beneficial effects observed with inhaled NO are mediated primarily through pulmonary vasodilation. Additional observed benefits include a reduction in platelet aggregation and neutrophil adhesion/sequestration in the lungs.⁶⁵⁻⁶⁷ NO is rapidly inactivated by binding to the heme moiety of hemoglobin. Due to its short half-life, NO does not enter the systemic circulation, making it an ideal selective pulmonary vasodilator.

The most common use of NO in the ICU is in the setting of acute respiratory distress syndrome (ARDS). Randomized control trials of varying sample size in ARDS have demonstrated improvement in oxygenation by improving the \dot{V}/\dot{Q} mismatch. NO improved the P_{aO_2} and $P_{aO_2}:F_{iO_2}$ ratios acutely but was no different than control by 24 to 72 hours.^{68,69} A reduction in mean pulmonary artery pressure was also observed in these trials with the use of NO. A beneficial trend was observed in a post hoc analysis in one trial in the more severe forms of ARDS.⁶⁸ However, a meta-analysis of controlled trials did not support the routine use of inhaled NO in ARDS and even suggested a possible increase in renal dysfunction.⁷⁰⁻⁷³ It can be considered as a treatment option in refractory cases of severe ARDS.⁷²

NO can be considered a "rescue" therapy to possibly allow for the institution of more protective forms of ventilation, with decreases in F_{iO_2} and mean airway pressures to maintain acceptable oxygenation. It might also be used in situations in which secondary pulmonary hypertension leads to compromised hemodynamic function from right ventricular failure.

Almitrine bismesylate enhances pulmonary vasoconstriction in areas of hypoxic vasoconstriction, thereby enhancing the redistribution of blood flow from shunt areas to lung units with normal \dot{V}/\dot{Q} ratios.^{74,75} This effect of almitrine therefore potentiates the effects of inhaled NO on gas exchange. Almitrine is not readily available in North America.

TABLE 64-2 Clinical Conditions Where Inhaled Nitric Oxide May Be Used

| |
|--|
| Acute respiratory distress syndrome |
| Severe primary and secondary pulmonary hypertension |
| Congenital cardiac syndromes |
| Right ventricular failure in acute pulmonary embolism or after cardiac surgery |
| Pulmonary ischemic-reperfusion injury after a heart-lung or lung transplant |
| Sickle cell crisis |

In addition to ARDS, other clinical conditions where NO use may be beneficial are listed in Table 64-2. Inhaled NO has been used following heart and lung transplants as a method to reduce right ventricular afterload in the setting of elevated pulmonary artery pressures.⁷⁶ In lung transplants, NO has been described to reduce the risk of ischemia-reperfusion injury. However, this effect was not supported by a randomized clinical trial in which NO was instituted early after lung transplantation.⁷⁷

Inhaled NO is typically initiated at low doses ranging from 1 to 2 ppm and gradually increased until the desired effect is achieved. One method recommended in the United Kingdom based on American-European Consensus Conference on ALI/ARDS guidelines is to perform a dose/response test starting at 20 ppm and reduce the concentrations to 10, 5, and 0 ppm to determine the lowest effective dose.⁷⁸ A significant response should be considered a 20% increase in the $\text{PaO}_2:\text{FiO}_2$ ratio or at least a 5 mm Hg decrease in the mean pulmonary artery pressure (PAP). Improvements in gas exchange are usually observed at lower doses than the reductions in PAP. The usual dose of inhaled NO ranges from 10 to 40 ppm. Doses greater than 80 ppm are associated with a higher risk for adverse effects.

Adverse effects of NO include the formation of methemoglobin and spontaneous oxidation to nitrogen dioxide (NO_2). NO_2 is toxic and causes airway irritation and hyperreactivity with levels as low as 1.5 ppm, as well as pulmonary edema and pulmonary fibrosis after exposure to higher levels. Despite these adverse effects, the development of methemoglobinemia or other toxicities related to NO_2 during acute or prolonged NO inhalation are unusual, especially when NO has been administered at concentrations less than 80 ppm.⁷⁹

To reduce the risk of exposure to NO_2 , NO should be stored at concentrations no higher than 1000 ppm in a pure nitrogen environment and only exposed to oxygen at the time of administration. NO should be delivered into the ventilator circuit as close to the patient as possible. NO and NO_2 levels should be monitored closely on the inspiratory side of the Y-piece when using doses above 2 ppm. Rebound pulmonary vasoconstriction can occur with sudden discontinuation, leading to a rapid worsening of \dot{V}/\dot{Q} mismatch and pulmonary hypertension with a significant hemodynamic collapse.⁸⁰

An absolute contraindication to NO therapy is a methemoglobinemia reductase deficiency (congenital or acquired). Relative contraindications include bleeding diathesis (secondary to reports of altered platelet function and bleeding time with iNO), intracranial hemorrhage, and severe left ventricular failure (NYHA grade III or IV).⁷⁸

Inhaled Prostaglandins

Inhaled prostaglandins I₂ (PGI₂) and E₁ (PGE₁) have similar effects to inhaled nitric oxide, with minimal systemic effects.⁸¹ PGE₁ has the advantage of more rapid degradation by pulmonary endothelial cells, providing a selective advantage over PGI₂ at higher doses.⁸² A recent meta-analysis did not find an improvement in the outcome for the routine use in ARDS⁸³ but they can be considered as alternatives for rescue therapy when used for conditions similar to those treated with iNO. As with iNO, care must be taken to avoid the abrupt discontinuation of PGI₂ or PGE₁ because pulmonary hypertension and cardiovascular collapse can rebound as a result.

Heliox

Helium is an inert gas with a significantly lower density than room air (1.42 g/L for oxygen versus 0.17 g/L for helium). By substituting helium for nitrogen, the degree of reduction in the density of the gas is directly proportional to the fraction of the inspired oxygen concentration in the mix. Heliox reduces the Reynolds number, increasing the laminar flow and reducing airflow resistance. Consequently, the work of breathing and dynamic hyperinflation associated with high airway resistance are reduced. Clinical situations where heliox may be used include conditions with high airflow resistance, such as severe acute asthma or COPD exacerbations, bronchiolitis, bronchopulmonary dysplasia, and extrathoracic or tracheal obstruction. Heliox has been used to improve lung compliance during noninvasive ventilation in COPD patients, to reduce the work of breathing, to avoid intubation, and to improve aerosolized drug delivery. In the management of moderate to severe asthma exacerbations, routine use of heliox is not supported by systematic reviews of the literature but can be considered as an adjuvant in severe cases. In COPD exacerbation, two multicentered trials found no difference in intubation rate or length of stay in the ICU when heliox was added to noninvasive ventilation.^{84,85} However, there appeared to be a cost benefit resulting from a shorter overall hospital length of stay.⁸⁴ Most studies utilize helium/oxygen mixes of 80:20 or 70:30 to achieve a therapeutic benefit. At higher concentrations of oxygen, the effect of helium declines and therefore heliox is limited to patients who are not severely hypoxemic. When used in conjunction with nebulized medications, higher flows of heliox may be required to ensure adequate delivery of the medication, though this may be offset by the smaller particle size generated in a heliox mixture. Ventilators also require a recalibration for measured FiO_2 , flows, and tidal volumes when using heliox.

SUMMARY

Pulmonary disease and complications are common in critically ill patients, especially those undergoing mechanical ventilation. It is important for the clinician to recognize these potential complications and the many forms of adjunctive respiratory therapies available to prevent further morbidity. Simple therapies, such as chest physiotherapy, suctioning, and positioning should be utilized in most patients, with more advanced procedures and therapies used on a selective basis based on the underlying clinical condition.

KEY POINTS

1. Inability to effectively clear secretions is common in critically ill patients, increasing the risk of aspiration, atelectasis, and pneumonia.
2. Chest physiotherapy, positional therapy, and early mobilization should be considered in all critically ill patients.
3. Other adjunctive forms of respiratory therapy should be considered on an individual basis based on the underlying clinical condition.
4. Aerosolization of medications is an effective way of direct delivery to the lungs.
5. Metered-dose inhalers (MDIs) are preferred over nebulization for the delivery of bronchodilators in both the spontaneously breathing and mechanically ventilated patient.
6. Inhaled nitric oxide is associated with improved pulmonary and cardiac physiologic parameters when administered in a variety of clinical conditions encountered in the ICU.
7. Heliox can be considered as adjuvant therapy in severe cases of airflow obstruction.

Hyperbaric oxygen (HBO₂) treatment involves intermittent breathing of pure oxygen at greater than ambient pressure (>1.4 atmospheres absolute [ATA]). Over the past 20 years, HBO₂ has undergone refinement, with an increased understanding of the mechanisms of action and clinical applications.

■ APPLICATIONS

HBO₂ treatment is carried out in either a monoplace (single person) or multiplace (typically 2 or more) chamber. Pressures applied while in the chamber are usually 2 to 3 ATA, representing the sum of the atmospheric pressure plus additional hydrostatic pressure equivalent to 1 or 2 atmospheres. Treatments are usually for 2 to 8 hours, depending on the indication and may be performed between 1 to 3 times daily. Monoplace chambers are usually compressed with pure oxygen. Multiplace chambers are pressurized with air and patients breathe pure oxygen through a tight-fitting face mask, hood, or endotracheal tube. During treatment, the PaO₂ typically exceeds 2000 mm Hg and levels of 200 to 400 mm Hg occur in tissues.¹

HBO₂ should be viewed as a drug and the hyperbaric chamber as a dosing device. Elevating tissue oxygen tension is a primary effect. Although this may alleviate physiologic stress in hypoxic tissues, lasting benefits of HBO₂ must relate to an abatement of the underlying pathophysiologic processes. The accepted indications comprise a heterogeneous group of disorders (Box 65-1), thus implying that there are several mechanisms of action for HBO₂ (Box 65-2).¹⁻³

Arterial Gas Embolism and Decompression Sickness

Among the earliest application of hyperbaric therapy was to treat disorders related to gas bubbles in the body. Compressed air construction work required exposure to elevated ambient pressure within compartments (caissons) for many hours to excavate tunnels or bridge foundations in muddy soil that otherwise would flood. In the 19th century, workers were noted to frequently experience joint pain, limb paralysis, or pulmonary compromise when they returned to ambient pressure. This condition—decompression sickness (DCS), caisson disease, or bends—was later attributed to nitrogen bubbles in the body and recompression was found to relieve symptoms. Recompression to treat DCS, based purely on Boyle's law with a reduction of gas bubble volume due to pressure, was later improved by adding supplemental oxygen to hasten inert gas diffusion out of the body. Similar observations were made at later times for scuba divers who are also prone to develop arterial gas embolism (AGE) due to pulmonary overpressurization on decompression.

Iatrogenic AGE has been reported in association with cardiovascular, obstetric/gynecologic, neurosurgical, and orthopedic procedures and generally whenever disruption of a vascular wall occurs. Nonsurgical processes reported to cause AGE include overexpansion during mechanical ventilation, hemodialysis, and after accidental opening of central venous catheters.⁴

Treatment of gas bubble disorders include standard support of airway, ventilation, and circulation plus prompt application of HBO₂. Gas bubbles have been reported to persist for several days, and although delays should be avoided, HBO₂ may be beneficial even when begun

after long delays.⁵⁻⁹ Controlled animal trials support the efficacy of HBO₂, but randomized clinical trials have not been conducted.¹⁰ In their review of 27 case series, Moon and Gorman described the substantial benefit of HBO₂ treatment, in which 78% of 441 cases receiving HBO₂ fully recovered and 4.5% died, whereas only 26% of 74 cases not undergoing HBO₂ treatment fully recovered and 52% died.⁴

Mechanisms of action of HBO₂ in AGE and DCS treatment include the reduction of gas bubble size according to Boyle's law, hyperoxygenation to hasten inert gas diffusion, and an additional effect related to inhibition of leukocyte adherence to injured endothelium. Endothelial dysfunction occurs in association with mechanical interactions of bubbles at vessel walls and lumen occlusion.¹¹⁻¹⁵ Neutrophil activation and perivascular adherence occur and are associated with functional deficits post decompression.^{16,17} Animals depleted of leukocytes before experimental cerebral air embolism suffer a less severe reduction in cerebral blood flow and better neurologic outcome.¹⁸ HBO₂ has been shown to temporarily inhibit human β_2 -integrin adhesion function.¹⁹ Inhibition of neutrophil β_2 -integrin adhesion by HBO₂ has been described in a number of animal models, including skeletal muscle ischemia-reperfusion, cerebral ischemia-reperfusion, pulmonary smoke inhalation injury, and brain injury after carbon monoxide (CO) poisoning.²⁰⁻²³ The mechanism for this effect involves S-nitrosylation of cytoskeletal β -actin, which impedes the coordinated cell-surface β_2 -integrin migration required for firm adherence.²⁴

CO Poisoning

CO is the leading cause of injury and death by poisoning in the world.²⁵ The affinity of CO for hemoglobin to form carboxyhemoglobin (COHb), is more than 200-fold greater than that of O₂. CO-mediated hypoxic stress is a primary insult, but COHb values correlate poorly with clinical outcome.²⁶⁻³² Pathologic mechanisms, in addition to elevations of COHb, include intravascular platelet-leukocyte aggregation, leukocyte-mediated oxidative injury to brain, the excessive release of amino acids (e.g., glutamate), impaired mitochondrial oxidative phosphorylation, and possible myocardial calcium overload.³³⁻³⁹

Survivors of acute CO poisoning are at risk for developing delayed neurologic sequelae (DNS) that include cognitive deficits, memory loss, dementia, parkinsonism, paralysis, chorea, cortical blindness, psychosis, personality changes, and peripheral neuropathy. DNS typically occurs from 2 to 40 days after poisoning and the incidence is from 25% to 50% after severe poisoning.

Administration of supplemental oxygen is the cornerstone of treatment for CO poisoning. Oxygen inhalation will hasten the dissociation of CO from hemoglobin, as well as provide enhanced tissue oxygenation. HBO₂ causes COHb dissociation to occur at a rate greater than that achievable by breathing pure oxygen at sea level. Additionally, HBO₂, but not ambient pressure oxygen treatment, has several actions that have been demonstrated in animal models to be beneficial in ameliorating pathophysiologic events associated with central nervous system (CNS) injuries mediated by CO. These include an improvement in mitochondrial oxidative processes,⁴⁰ inhibition of lipid peroxidation,⁴¹ and impairment of leukocyte adhesion to injured microvasculature.²² Animals poisoned with CO and treated with HBO₂ have been found to have more rapid improvement in cardiovascular status,⁴² lower mortality,⁴³ and diminished incidence of neurologic sequelae.⁴⁴

BOX 65-1**Accepted Indications for Hyperbaric Oxygen Therapy**

- Air or gas embolism
- Carbon monoxide poisoning
- Clostridial myositis and myonecrosis
- Crush injury, compartment syndrome, acute traumatic ischemia
- Decompression sickness
- Enhancement of healing in selected problem wounds
- Severe anemia
- Intracranial abscess
- Necrotizing fasciitis
- Refractory osteomyelitis
- Radiation necrosis
 - Delayed radiation injury
- Compromised skin grafts and flaps
- Thermal burns
 - Central retinal artery occlusion
 - Idiopathic sudden sensorineural hearing loss

Data from Weaver, LK, editor. Hyperbaric oxygen therapy indications. 13th ed. Durham, NC: Undersea and Hyperbaric Medical Society; 2014.

BOX 65-2**Mechanisms of Action of Hyperbaric Oxygen****RELATED TO HYPEROXYGENATION OF TISSUES**

- Angiogenesis/neovascularization/osteogenesis/epithelialization in ischemic tissues (mechanisms likely include O₂ behaving as intracellular signal transducer, leading to augmentation of one or more growth factors and mobilization of vasculogenic stem cells)
- Bacteriostatic/bactericidal actions
- Carboxyhemoglobin dissociation hastened
- *Clostridium perfringens* α toxin synthesis inhibited
- Phagocytic bacterial killing improved
- Temporary inhibition of neutrophil β_2 -integrin adhesion
- Vasoconstriction
 - Induction of growth factors and growth factor receptors
 - Inhibition of neutrophil adhesion
 - Reduction of ischemia reperfusion injury
 - Reduction in inflammation and edema

RELATED TO PRESSURIZATION

- Reduction of gas bubble volume (Boyle's law)

Despite online criticisms of their analysis, a meta-analysis by the Cochrane Library concluded that it is unclear whether HBO₂ reduces the incidence of adverse CO-mediated neurologic outcomes.⁴⁵ There are five prospective, randomized trials that have assessed the clinical efficacy of HBO₂ for acute CO poisoning.^{30,31,32,46,47} Several studies failed to find a benefit,^{30,47} but methodological weaknesses discussed by several authors^{39,48} diminish their clinical impact. Only one clinical trial satisfies all items deemed to be necessary for the highest quality of randomized controlled trials.⁴⁹ HBO₂ treatment also appears to diminish acute mortality based on a retrospective analysis.⁴⁸

In patients exposed to smoke and fire, careful attention needs to be paid to the patient's airway, and early intubation should be strongly considered. Some patients being treated for CO toxicity become more alert during HBO₂ therapy and therefore, in vented patients, adequate sedation should be prioritized due to the risk of dislodging the endotracheal tube and patient safety. Some burn centers employ adjunctive HBO₂ for severe burns. Animal models have documented benefits with HBO₂ in reducing partial to full-thickness skin loss, hastening epithelialization, and lowering mortality.¹ Randomized clinical trials, albeit with small patient numbers, have reported improved rates of healing of burns with shorter hospitalization stays and, therefore, reduced costs.⁷⁹⁻⁸² The rationale for treatment has been based on reducing tissue edema and increasing neovascularization.

Clostridial Myonecrosis (Gas Gangrene)

Successful treatment of gas gangrene depends on prompt recognition and aggressive intervention. Early treatment with HBO₂ is recommended to inhibit the production of alpha-toxin by *C. perfringens*. Mortality rates with conventional therapy from 11% to 52% have been reported. There are five retrospective comparisons using HBO₂ and 13 case series in the literature. These have been discussed in several reviews.^{1,54,55} Because of difficulties with comparison among patient groups, impartial assessment of HBO₂ efficacy based on mortality or "tissue salvage" rates is difficult. Most authors comment on clinical benefits associated with treatment. Temporal improvement of vital signs in patients with gangrene can be among the most dramatic observations in day-to-day practice.

Progressive Necrotizing Infections

The use of HBO₂ for treatment of necrotizing fasciitis and Fournier's gangrene, which are mixed aerobic-anaerobic infections, has been reported in six nonrandomized comparisons and four case series.⁶²⁻⁷¹ As with gas gangrene, variations in time of diagnosis and clinical status on admission compromise assessment of the existing literature. Most studies have reported that when HBO₂ is added to surgery and antibiotic therapy, mortality is reduced versus surgery and antibiotics alone. Animal trials have been difficult to assess because synergistic bacterial processes are difficult to establish. One report has found HBO₂ to potentiate antibiotics in streptococcal myositis,⁷² and several animal models of polymicrobial bacteremia and sepsis have reported increased survival with HBO₂.⁷³⁻⁷⁵ Mechanisms of action may include the suppressed growth of anaerobic microorganisms and improved bactericidal action of leukocytes (that function poorly in hypoxic conditions).^{11,76-78}

CRITICAL CARE IN HYPERBARIC MEDICINE

Plans for treatment begin while the patient is still in the intensive care unit, before transport to the hyperbaric chamber is initiated. Issues to be addressed include informed consent, a determination that all intravenous/arterial lines and nasogastric tubes/Foley catheters are secured, capping all unnecessary intravenous catheters, placing chest tubes to one-way Heimlich valves, and adequately sedating or paralyzing the patient as clinically indicated.

The environment of the hyperbaric chamber imposes limitations on equipment, including space restrictions, fire codes, and the effect of pressure on equipment function. Electrical components of equipment are located outside the hyperbaric chamber. Cables penetrate the chamber bulkhead to make a connection to the pneumatic portion of ventilators, internal cardiac pacer wires, electrocardiogram attachments, and arterial line transducers. The patient is attached to equipment at ambient pressure before treatment. Once the treatment pressure is achieved, all settings are checked and transducers recalibrated. It is especially important to remember to check the cuff pressure of endotracheal tubes. Many centers make it a practice to replace the air in these cuffs with an equivalent volume of sterile saline before treatment to avoid volume changes related to pressurization.

There are several intravenous infusion pumps that operate normally in the multiplace chamber environment. If glass bottles, pressure bags, or any other gas-filled equipment is used inside a hyperbaric chamber, it must be adequately vented and closely monitored during treatment. There are limited numbers of ventilator brands approved for the high-pressure environment and, generally, pressure cycle mode functions more reliably than volume cycle. Furthermore, patients with severe lung disease and high mean airway pressures often cannot be treated under hyperbaric conditions until pulmonary function improves.

Bed type, size, and timing of treatment around other procedures and diagnostic testing can limit the number of HBO₂ treatments the patient receives. The recent trend to place very ill patients with elevated

creatinine on continuous dialysis has also hindered the ability to treat patients at regular intervals.

ADVERSE EFFECTS

The inherent toxicity of O₂ and potential for injury due to elevations of ambient pressure must be addressed whenever HBO₂ is used therapeutically. Middle ear barotrauma is the most common adverse effect of HBO₂ treatment.⁹¹ As the ambient pressure within the hyperbaric chamber is increased, a patient must be able to equalize the pressure within the middle ear by auto-insufflation. Standard protocols include the instruction of patients on auto-insufflation techniques and adding oral or topical decongestants when needed. When these interventions fail, tympanostomy tubes must be placed. Intubated patients have difficulty with equalization, and the tympanic membrane must be examined after each treatment. The incidence of tube placement has been reported to be approximately 4% in one series.⁹² Others report an overall incidence of aural barotrauma to be between 1.2% and 7%.^{93,94}

Pulmonary barotrauma during HBO₂ treatment is extremely rare but should be suspected when any significant chest or hemodynamic symptoms occur during or shortly after decompression. Since the off-gassing of gas in virtually all cases will be pure O₂, absorption within the body may occur. If symptoms do develop, however, decompression should be prevented and the patient evaluated. If the pneumothorax is suspected, placement of a chest tube is appropriate. Preexisting pneumothorax should be treated with chest tube drainage before initiating therapy.

Biochemical toxicity due to O₂ can be manifested by injuries to the lungs, CNS, and eyes. Pulmonary insults can impair mechanics (elasticity), vital capacity, and gas exchange.⁹⁴ These changes are typically observed only when treatment duration and pressures exceed typical therapeutic protocols. CNS O₂ toxicity is manifested as a grand mal seizure. This occurs at an incidence of approximately 1 to 4 in 10,000 patient treatments.^{93,99,100} The risk is higher in hypercapnic patients and possibly those who are acidotic or compromised due to sepsis, because an incidence of 7% (23 in 322 patients) was reported in case series of HBO₂ treatment of gas gangrene.⁵⁴ Anecdotally, intubated patients seem to be at higher risk of seizures due to the greater amount of

oxygen to which they are exposed. Seizures are managed by reducing the inspired O₂ tension while leaving the patient at the same ambient pressure (to avoid pulmonary overexpansion injury when a patient is in tonic convulsion phase).

Progressive myopia has been reported in patients who undergo prolonged daily therapy, but this typically reverses within six weeks after termination of treatments.¹⁰² There is a risk for nuclear cataract development, most typically when treatments exceed a total of 150 to 200 hours, but they may arise with less provocative exposures.^{103,104} Although there is a theoretical risk of retrolental fibroplasia in neonates,¹⁰⁵ there are no reports of this having occurred. Currently, the experimental and clinical evidence does not indicate that typical HBO₂ therapy protocols have detrimental effects on neonates or the unborn fetus.¹⁰⁶ This is likely due to the relatively short duration of hyperoxia.

OTHER RISKS

Confinement anxiety may occur and is typically managed with the use of sedating agents. Any environment with an elevated concentration of O₂ presents a risk for fire. Scrupulous attention to avoiding an ignition source is standard in HBO₂ therapy programs.¹⁰⁷

KEY POINTS

1. Several therapeutic mechanisms of action for hyperbaric oxygen therapy stem from two fundamental effects: hyperoxygenation of perfused tissues and reduction of gas bubble volume.
2. Safe treatment of critically ill patients can be accomplished in either one-man "monoplace" or larger multiple-person hyperbaric chambers.
3. Efficacy of hyperbaric oxygen therapy has been documented by randomized clinical trials for a heterogeneous group of disorders.

ANNOTATED REFERENCES

Bennett MH, Feldmeier J, Hampson N, et al. Hyperbaric oxygen therapy for late radiation tissue injury. *Cochrane Database Syst Rev* 2012;(5):CD005005.

This meta-analysis surveyed 11 trials and concluded that for people with late radiation tissue injury affecting head, neck, anus, and rectum HBO₂ improved outcome.

Hampson NB, Piantadosi CA, Thom SR, et al. Practice recommendations in the diagnosis, management, and prevention of carbon monoxide poisoning. *Am J Respir Crit Care Med* 2012;186(11):1095-101.

The consensus opinion paper reviews current issues pertaining to acute CO poisoning. Based on data from the existing study with the best design that most closely addresses the actual practical handling of patients it concludes that HBO₂ should at least be considered in all cases of serious acute CO poisoning and normobaric 100% oxygen continued until the time of HBO₂ administration.

Londahl M, Katzman P, Nilsson A, et al. Hyperbaric oxygen therapy facilitates healing of chronic foot ulcers in patients with diabetes. *Diabetes Care* 2010;33(5):998-1003.

When clinicians discuss critical care, skin ulcers are rarely considered. However, the foot wound of a diabetic patient heightens the risk of cardiovascular and all-cause mortality beyond that associated with the metabolic derangements typically linked to diabetes. This blinded, prospective, randomized trial of 94 patients demonstrated that HBO₂ improved wound healing over 2-fold compared with placebo.

Imaging of the chest in critically ill patients is necessary for obtaining accurate diagnoses, as well as for evaluating the response to therapy and monitoring the placement and position of supportive devices. However, imaging of intensive care unit (ICU) patients is challenging, both technically and diagnostically.

Portable radiographs and computed tomography (CT) are the primary modalities used to evaluate critically ill patients. Both have limitations, however, when patients are immobile and mechanically ventilated. For example, the quality of portable bedside chest radiographs is diminished secondary to multiple factors, including anteroposterior (AP) projection, supine or semi-upright patient positioning, overlying supportive lines, tubes, and other life support devices. AP projection and a shorter source-to-image distance result in the magnification of the heart and mediastinum (Figs. 66-1, A, and 66-1, B).¹ The supine positioning of the patient can also make the heart and anterior mediastinal structures appear larger, as well as obscure pneumothoraces and posteriorly layering pleural effusions. Pulmonary vascular engorgement can also be overestimated in a supine patient.

Computed tomography provides better anatomic detail and a higher degree of diagnostic accuracy than plain film radiographs but is more difficult to obtain since it is not portable. CT scan quality can be limited by ventilator-assisted respiratory motion artifacts and beam-hardening artifacts from devices. Many patients in the ICU have diminished renal function, so IV contrast frequently cannot be used.

Interventional radiology has become an increasingly integral part of the approach to critically ill patients. Image-guided placement of vascular lines and pleural catheters, especially in the case of loculated pleural effusions, is common. Additionally, tissue sampling for pathologic evaluation is often performed under image guidance by the interventional radiologist (Table 66-1).

SUPPORT DEVICES

Multiple devices are routinely utilized in critically ill patients for monitoring and support (Table 66-2). Malposition of these devices can lead to significant morbidity and possibly death. Knowledge of the radiographic appearance of the equipment along with their correct placement is essential. Moreover, being familiar with potential complications related to each particular device is important.

Tracheal Tubes

Mechanical ventilation is required for the treatment of respiratory failure and includes placement of a cuffed endotracheal tube (ETT) or tracheostomy tube (TT) of appropriate size to ensure an adequate airway. ETTs are usually designated by a thin radiodense line along its length. The proper location of the ETT tip should be 3 to 7 cm above the carina with the patient's chin in a neutral position. This corresponds to the tip being located at approximately the level of the T3/T4 vertebral bodies. There can be up to 2 cm of displacement of the tube tip if the neck is in flexion or extension. Keeping the tip at the level of the clavicular heads is a good landmark. Inadvertent displacement of the ETT can occur into the esophagus, but more commonly, it is too deeply advanced into the airway so that its tip resides in either the right or left main stem bronchus. With esophageal intubation, there is usually

gaseous distention of the stomach on chest x-ray (CXR), and at times, the tube can be visualized lateral to the tracheal air column. When intubation of the main stem bronchus occurs, it is usually right-sided because of the shallow angle between the trachea and right main stem bronchus compared with the left. The contralateral bronchus can become obstructed by the low tube resulting in atelectasis or collapse of that lung, and the ipsilateral lung can become hyperinflated with an increased risk of pneumothorax. Too high a location for an ETT is also undesirable with the risk of vocal cord damage (Figs. 66-2 and 66-3).

Tracheostomy tubes are inserted surgically at the cricoid level. The tip should always be several centimeters above the carina. After insertion, gas in the soft tissues of the upper mediastinum and neck is common but should resolve quickly. Widening of the upper mediastinum after TT placement should raise concern for complications, such as bleeding and hematoma.

Pneumothorax after ETT and TT placement can also occur and should be evaluated on each CXR (Fig. 66-4). A tracheal laceration is an uncommon complication. Tracheal stenosis is a chronic complication of TTs, which can occur at the stoma site or at the site of the cuff, which is approximately 1.5 cm distal to the stoma.

Central Venous Catheters

Central venous catheters (CVC) are most commonly placed via a subclavian vein or internal jugular vein approach. They are routinely used for venous access and for measuring central venous pressures in critically ill patients. They are typically 6-8F in diameter. Knowledge of thoracic venous anatomy is useful in determining proper catheter placement or misplacement. The optimal location of the catheter tip is within the superior vena cava (SVC), located along the right parame-diastinum, from the level of the right first anterior intercostal space (which is past the last venous valve) to the cavoatrial junction (which is 1.5 to 2 vertebral body heights inferior to the carina).

Too inferiorly positioned catheters within the right atrium can result in an increased risk of cardiac perforation and arrhythmias. If the catheter tip hooks posteriorly in the right parame-diastinal region, it is likely within the azygos vein (Figs. 66-5, A, and 66-5, B) and should be retracted slightly back into the SVC. In patients with a left SVC variant, the catheter will course along the left parame-diastinal region and usually enters the right atrium by way of the coronary sinus.

Inadvertent arterial catheterization is usually suspected clinically because of bright red, pulsatile blood return, but an arterial course on CXR will assist in confirmation (Fig. 66-6).

Pneumothorax occurs up to 5% of the time with central venous catheter insertion and is most commonly observed with the subclavian approach (Fig. 66-7). Therefore, an upright chest radiograph should be obtained after each line insertion and, just as importantly, after a failed insertion attempt.² If there is a new apical opacity, mediastinal widening, or an enlarging unilateral effusion seen on the postprocedure radiograph, a localized hematoma or a hemothorax from venous or arterial damage should be suspected. Additionally, a CT scan, preferably with contrast enhancement to detect any active bleeding, may be necessary for confirmation. Rarely, CVCs can fracture with the free fragment usually migrating through the central veins and right heart chambers into the pulmonary arterial branches (Fig. 66-8).

FIGURE 66-1 ■ **A**, Posteroanterior (PA) upright chest x-ray. **B**, Anteroposterior (AP) supine view of the same patient. Note magnification of heart and mediastinum. Shallow inspiration increases vascular resistance making the perihilar and interstitial markings (pulmonary vessels) more prominent, as well as the azygos vein (*outlined by arrowheads*). AA, aortic arch; C, carina; DA, descending aorta; HD, hemidiaphragm; LA, left atrium; LMB, left main stem bronchus; LV, left ventricular border; RA, right atrial border; RMB, right main stem bronchus; RV, right ventricular body; S, stomach; T, trachea.

TABLE 66-1

Systematic Approach to Chest X-ray Interpretation

- Note projection (anteroposterior vs. posteroanterior), patient position (supine vs. upright, and a number of views).
- Determine the nature and location of all supportive devices and postoperative equipment.
- Evaluate heart size, contour, and location.
- Evaluate pulmonary vasculature.
- Assess the lung parenchyma and expected silhouettes.
- Assess the pleura.
- Evaluate the mediastinum and hilar regions.
- Evaluate the osseous structures.
- Check the visualized upper abdomen.

FIGURE 66-2 ■ Anteroposterior (AP) chest x-ray. Left MS (main stem) bronchus intubation with the collapse of the right lower lobe (RLL) and right middle lobe (RML) and rightward shift of the mediastinum. Arrow marks the “cutoff sign” of the distal right main stem bronchus. Note that with RML collapse, the hemidiaphragm and right atrial border are not seen as there is no longer an air interface. ETT, endotracheal tube; FT, feeding tube.

TABLE 66-2

Desired Location of Supportive Devices

ENDOTRACHEAL TUBE

- 3-7 cm above carina, ~T3/T4 vertebral body level, level of clavicular heads.

TRACHEOSTOMY TUBE

- Inserted at cricoid level; tip several cm above carina.

CENTRAL VENOUS CATHETERS TIP

- Distal superior vena cava to cavoatrial junction.

PULMONARY ARTERY CATHETERS TIP

- Right or left main pulmonary artery within 2 cm of pulmonary hilum.

CARDIAC PACEMAKERS AND AUTOMATIC IMPLANTABLE CARDIOVERTER DEFIBRILLATORS LEAD TIPS

- Right ventricle, right atrium, and through coronary sinus to cardiac vein.

THORACOSTOMY TUBE

- For effusion: Posteroinferior.
- For PTX: Anterosuperior.
- Side port inside lateral rib margin.

NASOGASTRIC TUBE TIP

- >10 cm past esophagogastric junction in left upper quadrant.

FIGURE 66-3 ■ Anteroposterior (AP) chest x-ray. Right main stem bronchus intubation with the collapse of the entire left lung and leftward shift of the mediastinum. In this case, the left hemidiaphragm and left ventricular border are no longer seen. The “collapse” is always opposite the side that is selectively intubated. Right perihilar air space opacities are due to “batwing” edema caused by acute myocardial infarction. Arrow marks the “cutoff” sign. ETT, endotracheal tube; RB, right main stem bronchus.

FIGURE 66-4 ■ Anteroposterior (AP) chest x-ray. Right main stem bronchus intubation resulting in a right pneumothorax (PTX), outlined by arrows. Background of interstitial pulmonary edema. Atelectasis and a pleural effusion obscure left hemidiaphragm and cause a “retrocardiac density.” CVC, central line; ETT, endotracheal tube.

FIGURE 66-5 ■ **A**, Posteroanterior (PA) chest x-ray. Placement of a central line (CVC) in the azygos vein. Arrow depicts the coiled CVC in the region of the azygos vein. **B**, Corresponding lateral chest x-ray. Note how the CVC takes a 90-degree posterior turn into the azygos arch (AA) before taking a 90-degree inferior turn into the descending azygos vein (DAV).

FIGURE 66-6 ■ Anteroposterior (AP) supine chest x-ray. Central line (CVC) that was placed in the right internal carotid artery instead of the right internal jugular vein. Instead of traveling straight downward along the right paramediastinum, the CVC courses obliquely across the superior mediastinum to the aortic arch (AA). AICD, automatic implantable cardioverter defibrillator; E, esophagus; LVAD, left ventricular assist device; T, trachea.

Percutaneous retrieval is necessary to prevent complications, such as vascular injury, occlusion, or cardiac arrhythmias.

Peripheral central venous catheters (PICC) frequently placed via an antecubital vein are smaller (2-5F) and more flexible. The risk of associated pneumothorax is, therefore, minimal. However, their increased flexibility leads to more frequent displacement, coiling, or kinking after placement, as well as to fractured fragments (Fig. 66-9).

Tunneled catheters are placed surgically, usually via a subclavian vein approach, and have a lower risk of infection. These catheters can become pinched between the clavicle and first rib resulting in difficult infusions, thrombosis, or fragmentation (Fig. 66-10). The tip position of PICCs and tunneled catheters is similar to that of standard CVCs.

Pulmonary Artery Catheters

Pulmonary artery catheters (PACs) (i.e., Swan-Ganz catheters) are used to monitor the cardiac and pulmonary hemodynamic status of critically ill patients. Proper placement is very important for accurate results. Usually inserted via an internal jugular (IJ) or subclavian approach, the tip is floated through the right heart chambers and into the main pulmonary arterial system, where it should remain when not in use (approximately 2 cm from the pulmonary hilum). When in use, the tip is advanced and “wedged” in a proximal interlobar artery where accurate pulmonary capillary pressures can be obtained that reflect left atrial pressure. Balloon inflation is required only at the time of measurement readings and should not be visualized on CXR as a ~1 cm round lucency at the catheter tip. A pulmonary infarct is not common but is the most frequent serious complication of PAC. This can result from a too peripheral location of the catheter (Fig. 66-11) or too prolonged inflation of the balloon. Pulmonary infarct on CXR presents as a new peripheral wedge-shaped or patchy airspace opacity corresponding to the lobe or segment in which the catheter was located. Pulmonary arterial pseudoaneurysm or perforation with hemorrhage and clinically presenting with hemoptysis are also rare complications of PACs.

FIGURE 66-7 ■ Anteroposterior (AP) supine chest x-ray. Large left-sided pneumothorax (PTX) with air noted around the left lung apex (large arrows), medially along the mediastinum (small arrows), and inferiorly, under the lung (white arrows). The latter results in the so-called “deep sulcus sign” (DSS) because costophrenic and cardiophrenic angles can be seen.

ECMO Catheters

Extracorporeal membranous oxygenation (ECMO) can be used for critically ill adults with respiratory failure. The technology of ECMO is similar to cardiopulmonary bypass but can be instituted at the bedside by placing a large bore (19-24F) catheter into the venous system to remove deoxygenated blood. The extracted blood then undergoes extracorporeal oxygenation before being returned to either the venous or arterial system via another large bore catheter. Venous access is typically through the right IJ vein or a femoral vein. Arterial access is typically through the right carotid artery or a common femoral artery (Fig. 66-12).

Implanted Cardiac Devices

Cardiac pacemakers and automatic implantable cardioverter defibrillators (AICD) are used for a variety of conduction abnormalities and to prevent sudden death from ventricular fibrillation. Insertion is usually via a transvenous approach, most commonly through the subclavian or IJ veins. One lead tip is placed within the right ventricle and should be located to the left of the midline on the frontal CXR and anteriorly on the lateral CXR. Additional lead tips are usually positioned within the right atrium, which is to the right of midline or through the coronary sinus into the middle or great cardiac veins,

FIGURE 66-8 ■ Anteroposterior (AP) supine chest x-ray. Catheter fragment (*arrow*) in a left lower lobe pulmonary artery branch.

FIGURE 66-9 ■ Anteroposterior (AP) supine chest x-ray. Left peripheral central venous catheter (PICC) courses cephalad from the left brachiocephalic vein into the left internal jugular vein, with its tip (*arrow*) residing in the mid neck. Note that the guide wire is within the PICC, making it very easy to see. Right internal jugular CVC tip in a good position at the cavoatrial junction (CAJ).

FIGURE 66-10 ■ Posteroanterior (PA) upright chest x-ray. Retained portacath fragment (*arrows*) within left brachiocephalic vein, superior vena cava, and right atrium is the result of shearing the catheter.

FIGURE 66-11 ■ Anteroposterior (AP) upright chest x-ray. Swan-Ganz catheter tip (*arrow*) is too distal, located in left lower lobe pulmonary artery. Background of cardiomegaly, interstitial and alveolar edema, and retrocardiac atelectasis.

FIGURE 66-12 ■ Anteroposterior (AP) supine chest x-ray. Diffuse bilateral airspace opacities in a patient with diffuse alveolar disease (DAD). Dual caval ECMO catheters noted in the SVC (superior vena cava) and IVC (inferior vena cava, marked with arrows). Bilateral chest tubes, ET tube, feeding tube, mediastinal drains, and mitral valve prosthesis also noted.

draping over the surface of the left ventricle. The generator pack is placed subcutaneously in the anterior chest wall.

It is always important to evaluate lead integrity after placement of a cardiac pacemaker or AICD. Fractures of the leads occur most commonly at one of three locations: near the tip, at the generator pack, or at the site of venous access.³ Myocardial perforation is another complication, and radiographic evidence of associated hemopericardium is suspected with progressive enlargement of the pericardial silhouette. Tamponade is usually diagnosed clinically but can be seen radiographically, with temporal pulmonary artery enlargement and engorgement of the vena cava.

Implantable loop recorders are small devices that are inserted under the skin to monitor the electrical activity of the heart continuously in the form of electrocardiograms. They do not require the use of implantable cardiac wires. Arrhythmic episodes are recorded and stored for extended periods to assist in the diagnosis of patients with syncope, seizures, and palpitations. They are rectangular in shape and most often located to the left of the sternum⁴ (Fig. 66-13).

Thoracostomy Tubes

Thoracostomy tubes are available in multiple diameters and degrees of flexibility. They are used to evacuate air and/or fluid from the pleural space. Correct placement of the tube depends on the type of substance being drained. To drain pleural fluid, the tube typically needs to be located posteroinferiorly. To relieve a pneumothorax, an anterosuperior location is usually best.

Chest CT is superior to CXR in accurately determining the course of thoracostomy tubes and noting their relationship to pleural air and fluid collections (Figs. 66-14, A, and 66-14, B). When loculations or adhesions are present, CT or ultrasound may be necessary as guidance for optimal tube placement.

The thoracostomy tube's side port is distinguished as a focal disruption of the radiopaque linear marker that runs the length of the tube and should always be located inside the rib margin (Fig. 66-15). If the side port is not within the rib margin, a pneumothorax and/or subcutaneous emphysema may develop. Inadvertent intraparenchymal

FIGURE 66-13 ■ Posteroanterior (PA) chest x-ray. Implantable loop recorder (LR) is in the soft tissues of the anterior left chest wall.

placement can result in laceration, hematoma, or bronchopleural fistula. Malfunction of the tube can occur when incorrectly positioned in a fissure or within the subcutaneous tissues, or when occluded by clot or debris.

Thoracostomy tubes are typically placed during thoracic surgery to be removed 1 to 2 days later. In postcardiac surgery patients, an anterior mediastinal drain that runs parallel to the sternum is common, as are pericardial and posterior-inferior mediastinal tubes, which usually are present at right angles to the sternum. Thin epicardial pacing wires placed through the chest and anchored in the myocardium are usually seen on the postoperative CXR. At the midline, thin epidural analgesic catheters or spinal neurostimulator wires can also be visualized (Fig. 66-16).

Enteric Tubes

Many critically ill patients who require gastric suction or enteric feedings are sedated or neurologically impaired, resulting in a depressed cough reflex. Inadvertent passage of enteric tubes into the tracheobronchial tree may be clinically unrecognizable. Radiographic confirmation of correct enteric tube position is, therefore, prudent before feeding or suction can begin. Nasogastric (NG) and feeding tubes (FT) each have a characteristic radiographic appearance. Gastric tubes are larger in diameter and have a linear radiopaque stripe along their entire length, apart from their side ports. Feeding tubes are thinner and longer without a radiopaque strip but instead contain a short cylindrical weighted metallic tip.

Enteric tubes can be displaced into the tracheobronchial tree or coiled within the hypopharynx, as well as being malpositioned (usually too proximally) within the enteric system (Fig. 66-17). The NG tube side hole is usually 10 cm from the tip and should be located well below the esophagogastric (EG) junction. A side hole proximal to or at the EG junction often leads to the aspiration of gastric contents (aspiration pneumonia), the postobstructive collapse of a lung or lobe, and to superimposed pneumonia. Feeding tube tips should be positioned in the duodenum or proximal jejunum to avoid reflux of feedings, which can also lead to increased risk of aspiration (Fig. 66-18). Since the enteric tubes are inserted over a wire, there is a potential risk of esophageal or gastric perforation. Displacement of the wire into the airway can result in pneumothorax.

FIGURE 66-14 ■ **A**, Anteroposterior (AP) supine chest x-ray. Chest tube tip (*large arrow*) appears to be within the right chest cavity. Note that the side port (*small arrow*) overlies the right lateral ribs and does not appear within the hemithorax. Right pleural effusion obscures right hemidiaphragm. **B**, Axial computed tomography (CT) slice. Same patient showing chest tube tip (*small arrow*) is actually outside of chest cavity within the soft tissues of the back.

Left Ventricular Assist Devices

An intraaortic counterpulsation balloon (IACB) is used to assist with severe left ventricular dysfunction by reducing systolic afterload and augmenting coronary artery perfusion. It consists of a 16- to 20-mm long inflatable balloon surrounding the distal end of a vascular catheter. It is usually inserted percutaneously through the femoral artery or directly into the thoracic aorta.

At the distal tip of the IACB, there is a small radiopaque cylindrical marker to help locate and position the catheter. When properly positioned, the tip should be located distal to the left subclavian artery in the proximal descending thoracic aorta, just below the bottom of the aortic arch (Fig. 66-19). The balloon itself is not typically visible on the CXR because it is either deflated or sometimes filled with water.³

When the IACB is advanced too far, the catheter can obstruct or occlude the left subclavian or left common carotid artery. If not advanced far enough, the balloon will be too distal relative to the

FIGURE 66-15 ■ Anteroposterior (AP) supine chest x-ray. Left chest tube has not been advanced adequately with the side hole outside of rib margin (*arrow*).

FIGURE 66-16 ■ Anteroposterior (AP) supine chest x-ray. Immediate postoperative coronary artery bypass graft chest x-ray with classic left lower lobe atelectasis, partially obscuring the left heart border and the left hemidiaphragm. Endotracheal tube (ETT), nasogastric tube (NGT), bilateral chest tubes (*black arrows*), and Swan-Ganz catheter (*black arrowhead*) are all in a good position.

proximal aorta, and counterpulsation will be less effective. There is also the risk of occluding the mesenteric and/or renal vessels, resulting in ischemia.

Aortic dissection following IACB insertion is another potential complication, especially in patients with pronounced aortic atherosclerotic

FIGURE 66-17 ■ Anteroposterior (AP) supine chest x-ray. Feeding tube (FT) courses through the trachea and then down the right bronchial tree to lodge in the peripheral lung.

FIGURE 66-18 ■ Anteroposterior (AP) supine abdomen x-ray. Feeding tube tip (white arrow) is at the level of the fourth distal portion of the duodenum.

disease or tortuosity, and should be considered when there is new mediastinal widening and/or loss of definition of the descending thoracic aorta on the CXR.

Left ventricular assist devices (LVAD) are typically implanted for three purposes: as a bridge to transplantation, as a therapy for patients ineligible to receive a transplant, and as a bridge to myocardial

FIGURE 66-19 ■ Anteroposterior (AP) supine chest x-ray. Intraaortic balloon pump (IABP) is in proper position with a proximal cylindrical marker (white arrow) just below the aortic arch (AA). When the x-ray was taken, the balloon happened to be inflated and can be easily recognized (outlined by smaller black arrows). Endotracheal tube (ETT) is also present and in the proper position.

recovery. CT scan of the chest is currently used as a problem-solving tool when echocardiography for LVAD evaluation is inconclusive. electrocardiography-gated CT of an LVAD should show the inflow cannula entering the left ventricular apex and directed into the left ventricular cavity without obstruction or surrounding thrombus formation, a neutral intraventricular septum, closure of the aortic valve during systole and diastole, and minimal to no aortic valve regurgitation. The outflow cannula will attach to the ascending or descending thoracic aorta (Fig. 66-20).⁵

The Impella is a percutaneously inserted ventricular assist device which is placed via a retrograde approach across the aortic valve using femoral artery access or via mini-thoracotomy (Figs. 66-21, A, and 66-21, B). It pumps blood from the left ventricle into the ascending aorta and systemic circulation. The device should straddle the aortic valve with the inflow tip (distal end of the catheter) residing in the left ventricular cavity and the outflow end in the proximal aorta.^{6,7}

CARDIOVASCULAR SYSTEM

As was discussed in the introduction, the patient's position will affect the cardiac size, as well as the appearance of the vasculature. Additionally, the cardiac silhouette appears approximately 12.5% larger on AP vs. posteroanterior (PA) images.¹ The same is true if the patient is rotated or if the CXR is taken in a lordotic view. Similarly, the phase of the respiratory cycle, specifically if the radiograph is not acquired during end-inspiration, will change the appearance of the heart and vasculature. In all of these cases, the heart will appear larger and the vasculature "plumper" and more ill-defined. When standing, the lower lobe pulmonary vasculature is normally larger in diameter than the upper lobe vasculature. However when supine, due to gravity, the blood flow is normally redirected posteriorly, and the differential appearance between the upper and lower lobe vascularity is not present.

FIGURE 66-20 ■ Anteroposterior (AP) supine chest x-ray, intraoperative. Detached left ventricular assist device (LVAD) outflow cannula (gap between arrowhead and arrow). Also, note an esophageal probe (ENDO) and a left upper quadrant surgical sponge (S).

When evaluating the cardiovascular system, the cardiac silhouette should be less than 50% of the transverse dimension of the lower thorax in the end-inspiration. A big “heart” may in fact not be cardiomegaly but a normal size heart with surrounding pericardial effusion. Here is where temporal analysis with a baseline “well patient” CXR coupled with clinical history becomes critical.

If there is global enlargement of the heart, it is usually due to an ischemic cardiomyopathy (ICM), a dilated cardiomyopathy (DCM), or multivalvular disease. The presence of pulmonary edema, diastolic dysfunction, or stenotic or regurgitant murmurs, coupled with the patient’s history, almost always establishes the correct diagnosis. Focal enlargement of the heart, in which one or two chambers are enlarged, is most commonly seen with LV enlargement due to ischemic disease, with or without a true aneurysm, single valve disease, cardiac tumors, or congenital heart disease.

■ LUNG PARENCHYMAL OPACITIES

Pulmonary Edema

Serial CXRs provide an assessment of the changing pulmonary vascular blood volume; evaluation of the temporal pattern is helpful in regards to response to therapy and aiding in an accurate diagnosis. Additionally, differentiating cardiogenic from noncardiogenic pulmonary edema is important, but challenging, in the critical care setting.

Cardiogenic Edema

In cardiogenic edema, Swan-Ganz catheter measurements provide a reliable measurement of cardiac function. There are correlating CXR findings as capillary wedge pressure increases and transudation of fluid into the interstitium and alveoli occurs (Table 66-3).

Initially, there is central peribronchial cuffing/thickening with pulmonary capillary wedge pressure (PCWP) of 12 to 18 mm Hg in a patient with normal intravascular oncotic values. The upper lobe

FIGURE 66-21 ■ **A**, Anteroposterior (AP) supine chest x-ray. Impella device properly positioned, straddling the aortic valve plane (AVP). **B**, Anteroposterior (AP) upright chest x-ray. Same patient after undergoing surgery via a sternotomy to replace the impella with an LVAD (bottom right arrow). Right, PICC line now coiled at right axillary vein level (top left arrow). Cardiomegaly and bibasilar subsegmental atelectasis.

TABLE 66-3 Cardiogenic Edema

PULMONARY CAPILLARY WEDGE PRESSURE (PCWP) = 12-18 MM HG

- Central peribronchial cuffing
- Cephalization/engorgement of central pulmonary arteries

PCWP = 18-25 MM HG

- Interstitial prominence with Kerley A and Kerley B lines

PCWP = >25 MM HG

- Alveolar opacities
- Cardiomegaly
- Pleural effusions

arteries become engorged (or “capitalized”) and appear to be the same or greater diameter than the respective inferior lobar vessels in a vertically obtained radiograph. To aid in establishing the volume of pulmonary blood flow, comparing the diameters of the central pulmonary arteries and the adjacent bronchus on end is useful. The normal ratio is 1:1 or less. An increase in this ratio reflects increased pulmonary flow/pressure. With further increasing PCW pressure to 18–25 mm Hg, fluid then accumulates within interlobular septa, as demonstrated by prominent horizontal linear opacities. These have been termed *Kerley A lines* when they are longer and perihilar in location and *Kerley B lines* when finer and extended to the pleural surface. Finally, when the wedge pressure exceeds 25 mm Hg, alveolar edema occurs, presenting as fluffy perihilar or basilar-dependent airspace opacities (Figs. 66-22, A, 66-22, B, and 66-22, C). The airspace opacities in cardiogenic edema can fluctuate rapidly, which can be a clue to diagnosis.⁸ Cardiomegaly and pleural effusions are also usually present with cardiogenic edema. Sometimes, there can be a lag in the radiographic improvement of cardiogenic edema relative to the pulmonary artery catheter pressures, which is thought to be related to the fact that it can take hours or days for large amounts of extracellular fluid to be reabsorbed.

The distribution of interstitial and airspace opacities in pulmonary edema is usually symmetric and dependent. However, opacities associated with pulmonary edema can be asymmetric, usually related to gravity and patient positioning. Underlying emphysema or chronic interstitial lung disease can also make edema appear patchy in its distribution.

Noncardiogenic Edema

Causes of noncardiogenic edema include neurogenic edema, renal disease, and global fluid overload, re-expansion edema, sepsis with increased capillary permeability, and rarer causes, such as fat embolism or other types of chemical pneumonitis⁹ (Table 66-4).

Neurogenic edema usually develops within hours to days after a neurologic insult, which can include trauma, stroke, seizure or intracranial hemorrhage, mass, or infection. The etiology of pulmonary edema in these settings is felt to be related to elevated microvascular pressure and increased pulmonary vascular permeability. It is postulated that a massive sympathetic discharge causes a surge of catecholamines resulting in cardiopulmonary dysfunction. The key to diagnosis is temporal, as there is usually a rapid clearance of bilateral airspace disease after the resolution of the cerebral edema/insult. Cardiomegaly and vascular engorgement are absent.^{10,11}

Edema from renal disease is related to an overall fluid overload state. Cardiomegaly, vascular cephalization, and effusions are commonly observed.

Re-expansion edema is due to the rapid re-expansion of a collapsed lung. It is unilateral and follows the drainage of pleural effusion or pneumothorax. It is more likely to occur when a large volume of pleural fluid or air is removed and if the affected lung has been chronically collapsed. Cardiomegaly is not an associated finding (Fig. 66-23).

Fat embolization is a rare complication of severe long bone fracture and is usually diagnosed clinically based on the trauma history. Dyspnea, altered mental status, and petechiae develop 12 to 72 hours after the initial injury. Chest imaging findings can be similar to pulmonary edema and organizing pneumonia (OP) with airspace geographic opacities, usually ground glass. This appearance is likely related to pneumonitis and increased capillary permeability (Figs. 66-24, A,

and 66-24, B). Cardiomegaly and vascular engorgement are absent. Low-density fat-filling defects in the pulmonary arteries are only very rarely seen.³

Pulmonary Contusion

Pulmonary contusion is a frequent complication following chest trauma and usually presents within six hours of the incident (Figs. 66-25, A, and 66-25, B). Radiographically, contusion (or focal hemorrhage/bruising of the lung parenchyma) presents as peripheral airspace opacities typically located deep to the site of chest wall impact. Associated adjacent rib fractures are also commonly seen. The opacities related to contusion usually clear rapidly; within 24 to 72 hours. Laceration, or disruption of the lung parenchyma, can accompany a contusion and present as focal ovoid radiolucencies within the contused portion of the lung.³ These are also referred to as traumatic pneumatoceles. Hemorrhage can fill the cavity, producing an opaque hematoma. Lacerations and associated hematomas usually resolve slowly over weeks to months (Table 66-5).

Diffuse Alveolar Disease/Organizing Pneumonia

The lung's response to injury, despite numerous offending agents, shows a similar radiographic pattern regardless of the underlying cause. Similarly, histologic features are similar with many insults leading to damage of the alveolar epithelial basement membrane and organization, characterized by fibroblast proliferation. This pattern is seen in diffuse alveolar damage (DAD) and OP (Table 66-6).¹² In most circumstances, the organization clears as part of the normal process of repair. However, in some instances, repair is self-reinforcing and leads to fibrosis.

The acute phase of DAD appears as diffuse or patchy geographic ground glass opacities (GGO) with areas of consolidation and septal thickening on CXR and CT. The distribution is most pronounced in the dependent portions of the lungs (Fig. 66-12). Fibrotic disease in the setting of chronic lung injury can progress to reticulation and traction bronchiectasis, which are most pronounced in the anterior, non-dependent portions of the lung. This distribution may be related to

FIGURE 66-22 ■ **A**, Anteroposterior (AP) upright chest x-ray. Emphysema is evidenced by hyperexpansion and attenuation of the upper lobe pulmonary arteries and veins. AA, aortic arch; AP window, aortopulmonary window; LPA, left pulmonary artery; RPA, right pulmonary artery. **B**, Anteroposterior (AP) upright chest x-ray: +3½ hours. Same patient 3½ hours later with redistribution of the pulmonary vasculature to the upper lobes, interstitial pulmonary edema as evidenced by indistinctness of the pulmonary vessels and “peribronchial cuffing,” a small right pleural effusion, and developing cardiomegaly. **C**, Anteroposterior (AP) supine chest x-ray: +4½ additional hours. Same patient 4½ hours later with diffuse but symmetric airspace opacities consistent with fluid filling the alveoli. Increasing pleural effusions are now layering posteriorly, giving a “whiter” appearance to the mid and lower hemithoraces. CVC, right internal jugular vein central venous catheter; ETT, endotracheal tube; NGT, nasogastric tube.

barotrauma due to mechanical ventilation or oxygen toxicity, whereas the dependent lung is protected from collapse^{13,14} (Table 66-6).

Historically, “OP” was used to describe the lung responses to pulmonary infection, though many other cases are recognized now. In the absence of an identifiable cause, the clinical diagnosis of cryptogenic OP (COP) can be made.^{15,16}

In most OP cases, there are diffuse, bilateral consolidative, and ground glass infiltrates. These are typically peripheral or peribronchocentric and frequently with interspersing areas of normal, unaffected

lung. The “reverse halo” and “atoll” signs on CT can be seen with OP and are characterized by GGO surrounded by a rim of denser consolidated opacity.¹⁷

Cardiomegaly and pulmonary vascular engorgement/cephalization are absent. Otherwise, the radiographic features of DAD and OP can be indistinguishable from pulmonary edema. Effusions are uncommon. Barotrauma with pneumothorax is more common with DAD because of reduced lung compliance and prolonged mechanical ventilation.^{18,19}

FIGURE 66-23 ■ Axial computed tomography (CT) slice through lower chest. Localized interstitial and airspace opacities in the right lower lobe after drainage of the pleural fluid collection. Small pleural effusion persists.

Pneumonia/Aspiration

The diagnosis of pneumonia is often clinical, based on the presence of fever and leukocytosis. However, new or progressive pulmonary opacification on CXR can aid in diagnosis. Nosocomial bacterial pneumonia can complicate the clinical course of up to 40% of ventilated patients.³ Proper antibiotic therapy with improvement in clinical symptoms may not alter the radiographic course of pneumonia for up to 48 hours after initiation. However, there should be a lack of progression, if not an improvement, in the radiographic abnormality after that point.

The risk of nosocomial pneumonia is much greater in patients who require intubation and mechanical ventilation than those who do not.²⁰ This is because the tracheal tube bypasses the usual upper airway defenses. Additionally, pharyngeal secretions and flora can leak around the cuff and enter the lower respiratory tract. Swallowing is impaired resulting in retention of secretions. The mechanical trauma to the tracheal epithelium also may predispose to opportunistic organisms. Aspiration can occur more easily in the presence of nasogastric tubes and ETTs, both of which are common in ICU patients.

The radiographic appearance of pneumonia includes the opacity of an entire lobe with or without air bronchograms (Figs. 66-26, A, and 66-26, B), confluent airspace opacities within a portion of a lobe, patchy and ground glass air space opacities, or endobronchial thickening with peribronchocentric opacities (Table 66-7).

Hospital-acquired pneumonia is more likely to be bilateral and multifocal than community-acquired pneumonia.²⁰ Cavitation and

TABLE 66-7 Pneumonia

- Opacity of entire lobe, with or without air bronchograms
- Confluent airspace opacities
- Patchy and ground glass airspace opacities
- Endobronchial thickening with peribronchocentric opacities
- Cavitation and necrosis of parenchyma
- Pleural effusion and empyemas
- Interstitial or nodular pattern with atypical organisms
- Peripheral cavitary opacities with septic emboli
- Dependent location suggests aspiration

associated empyema can occur with bacterial and mycobacterial infections and are more common with nosocomial organisms than with community-acquired ones.

Atypical pneumonia includes viral, fungal, and mycobacterial etiologies, which are commonly seen in immunocompromised patients. Viral pneumonia can present as diffuse nodules or linear interstitial reticulation, as well as airspace consolidations. Fungal pneumonia can appear as nodules or as focal, patchy consolidations and ground glass opacities. Mycetomas, or fungus balls, can develop within preexisting cavities.

Septic emboli are typically present as multiple, bilateral, peripheral ill-defined or wedge-shaped opacities, some of which may cavitate

(Figs. 66-27, 66-28, and 66-29). Common sources of septic emboli include infected tricuspid and pulmonic valves or indwelling catheters, along with sepsis and urinary tract infections.

Aspiration pneumonia or pneumonitis is most common in patients with a decreased level of consciousness, those who have ETTs in place, and those with esophageal or swallowing disorders. Aspiration usually presents as airspace opacity within the dependent portions of the lungs, which in a supine patient are the posterior basilar and superior segments of the lower lobes and the posterior segments of the upper lobes (Fig. 66-30). The degree and location of the opacification are dependent on the volume and nature of the aspirate, in addition to the position of the patient. For example, when acidic gastric contents are aspirated, a chemical pneumonitis resembling pulmonary edema can occur. Whereas when infected mucoid material from the upper airway is aspirated, the appearance is a combination of volume loss and a denser opacity resembling pneumonia.^{3,20} Associated atelectasis can also occur secondary to bronchial obstruction by the aspirated material.

Atelectasis

Atelectasis is a common finding in critically ill and postoperative patients. It is often associated with general anesthesia and frequently occurs following thoracic and upper abdominal surgery. It represents areas of nonaerated lung with the extent ranging from subsegmental linear bands, platelike or patchy opacities, to full lobar collapse. Air bronchograms may or may not be present, and the appearance can be indistinguishable from pneumonia. When suspected atelectasis persists beyond the third or fourth postoperative day, pneumonia becomes more likely. However, atelectasis comes and goes more rapidly than pneumonia and aspiration pneumonitis, usually within hours rather than weeks or days. Secondary findings of volume loss, such as diaphragmatic elevation and tenting, displaced fissures, crowding of the bronchovascular structures, and in more severe cases, deviation of the heart and mediastinum toward the atelectatic side may occur. The left lower lobe is the most common location for atelectasis.²⁰ After cardiac surgery, left lower lobe atelectasis is a frequent finding secondary to phrenic nerve damage from stretching and cold-induced trauma (Fig. 66-16 and Table 66-8).

Thromboembolism

Acute pulmonary embolism (PE) is a potentially lethal condition and is more common in hospitalized patients due to immobility, postoperative status, chemotherapy and other medications causing hypercoagulability, and additional comorbidities. Conventional chest radiograph findings are inconsistently present and nonspecific. CT angiography of the pulmonary arterial system has, therefore, become the gold standard for detection of pulmonary emboli. Filling defects, partial or complete, within the pulmonary arteries, are diagnostic of PE. Associated findings include pleural effusion, atelectasis, wedge-shaped peripheral pulmonary infarction (Hampton's Hump), local oligemia (Westermarck sign), and reperfusion edema (Figs. 66-31, A, 66-31, B, and 66-32). Secondary pulmonary artery hypertension with enlargement of the main pulmonary artery and evidence of right heart strain with left convex bulging of the intraventricular septum and engorgement of the vena cava and hepatic veins can be present.

PLEURAL DISEASE

Pleural Fluid

In the ICU, pleural effusions are common but may go undetected on supine CXRs, even when moderately sized. Fluid usually settles dependently in the posterior base when supine and may present as a homogeneous increase in the overall density of the lower hemithorax, blunting of the costophrenic angle, and loss of diaphragmatic contour. On an upright CXR, pleural fluid collections that are uncomplicated

FIGURE 66-26 ■ **A**, Posteroanterior (PA) upright chest x-ray. Airspace opacity within the right middle lobe (RML) caused by pneumonia (*outlined by arrows*). Note indistinct right heart margin suggesting the involvement of the medial segment of the RML. **B**, Lateral upright chest x-ray. Airspace disease located between the minor fissure (*upper arrows*) and the right major fissure (*lower arrows*) caused by a right middle lobe pneumonia.

FIGURE 66-27 ■ Axial computed tomography (CT) slice. Multiple bilateral peripheral cavitary nodules due to septic emboli.

FIGURE 66-28 ■ Anteroposterior (AP) supine chest x-ray. Bilateral focal lucencies (*black arrows*) within areas of airspace opacity suggest septic emboli or parenchymal necrosis. There is an associated right pneumothorax (white arrowhead delineates lung edge). ETT, bilateral internal jugular CVCs (central venous catheters), bilateral chest tubes, and NGT (nasogastric tube) are in proper position. Subcutaneous emphysema (SCE) is secondary to recent chest tube insertion.

FIGURE 66-29 ■ Axial computed tomography (CT) slice at level of aortic arch. Large, thick wall cavities in the periphery of both lungs with associated left pneumothorax (PTX) in a patient with tricuspid endocarditis, consistent with septic emboli.

FIGURE 66-30 ■ Anteroposterior (AP) supine chest x-ray. Bilateral lower lobe patchy airspace opacities in an intubated patient are the result of aspiration pneumonia/pneumonitis. ETT, endotracheal tube; NGT, nasogastric tube.

FIGURE 66-31 ■ **A**, Posteroanterior (PA) upright chest x-ray. Peripheral wedge-shaped opacity in the left upper lobe (*white arrow*). **B**, Sagittal computed tomography (CT) reconstruction. CT in same patient showing left upper lobe infarct and hemorrhage (*black arrows*) with an embolus in the left upper lobe segmental artery supplying this region (*white arrow*).

FIGURE 66-32 ■ Axial computed tomography (CT) slice at the level of the hila. Saddle embolus (*black arrow*) in the distal main pulmonary artery, straddling the entire length of the right and left main pulmonary arteries. Occlusive pulmonary embolism also noted in a left upper lobe segmental branch (*white arrow*).

and free flowing will present as a basilar opacity with a well-defined convex downward superior border and blunting of the costophrenic angle. As the effusion increases in size, it will track upwards resulting in a widening of the lateral pleural stripe and eventually apical “capping.” Bedside maneuvers, such as lateral decubitus films or cross table lateral films, can sometimes help determine the presence of pleural fluid and whether or not such fluid is free flowing vs. loculated (Fig. 66-33). A bedside ultrasound can also aid in detecting and characterizing pleural fluid collections and can assist with thoracentesis and pleural catheter guidance. CT is far superior to CXRs in evaluating complicated pleural fluid and gas collections.

Pleural effusions secondary to congestive heart failure and traumatic hemothorax are the most common etiologies of pleural fluid in the critical care unit. Other etiologies include pneumonia, pulmonary embolus, neoplasm, postoperative from median sternotomy or thoracotomy, and intraabdominal pathologies such as pancreatitis or hepatitis. Empyema is strongly suspected in the setting of pneumonia when the effusion is loculated and contains gas (Table 66-9).

Following trauma, pleural fluid collections are usually due to hemorrhage (hemothorax). Hemothorax from aortic rupture at the isthmus is left sided and can be associated with a left pleural cap. Vascular injury following central line placement or an attempt can also lead to pleural fluid accumulation. In these scenarios, there is a rapid accumulation of the fluid collections (Table 66-5).

Diaphragmatic rupture can occur after severe trauma and is usually left sided. It presents as an apparent elevation of the hemidiaphragm

FIGURE 66-33 ■ Right lateral decubitus chest x-ray. Right lateral decubitus film showing right pleural effusion loculated inferiorly and medially (LPE), free flowing laterally (*arrows*), and extending into the minor fissure (*arrowhead*).

TABLE 66-9 Pleural Effusions

- Transudative—congestive heart failure, fluid overload most common; simple (0–32 HU) fluid density
- Exudative—cancer, infection, collagen vascular disease most common; slightly higher density (21–28 HU)
- Bloody—hemothorax after trauma, aortic rupture, line placement; higher density (21–28 HU)
- Purulent—empyema; can be loculated and contain gas (and may have enhancing rim)
- Chylous—milky; lower density than simple fluid (<0 HU)

from abdominal organs becoming displaced into the thoracic cavity or as a basilar lucency due to portions of gas containing colon or stomach projecting above the hemidiaphragm (Fig. 66-34). Diagnosis can be confirmed with CT, which can often reveal a discrete diaphragmatic defect.³ In patients receiving mechanical ventilation, there can be a delay in diagnosis because of the positive pressure gradient between the thoracic and abdominal cavities.

After pneumonectomy or lobectomy, the vacant space within the hemithorax should fill with fluid from chest wall bleeding, transudation from the plural surface, or lymphatic leakage. Ipsilateral diaphragmatic elevation, mediastinal shift, and hyperexpansion of the residual lung also helps to fill the residual space. Total obliteration of the pleural space usually takes several weeks. Small air leaks are not uncommon in the immediately postoperative period and usually close spontaneously with conservative management. However, one should be concerned that a bronchopleural fistula has developed with the following findings: progressive pneumothorax and failure of the hemithorax to fill with fluid; a drop of 2 cm or more in a preexisting air-fluid level; and a contralateral shift of the mediastinum or depression of the ipsilateral hemidiaphragm (Fig. 66-35).

FIGURE 66-34 ■ Anteroposterior (AP) supine chest x-ray. Diaphragmatic rupture: “collar” sign with narrowing of the left juxtadiaphragmatic mass (*black arrows*) with the spleen and stomach protruding through the left hemidiaphragm defect into the left hemithorax.

FIGURE 66-35 ■ Posteroanterior (PA) upright chest x-ray. Persistent and increasing left pneumothorax (*white arrowheads*) 2 months after lobectomy, despite the presence of a small bore pigtail tube in lower left hemithorax, suggests the presence of a bronchopleural fistula.

Pleural Gas

Pneumothorax due to barotrauma is a common complication in patients supported by mechanical ventilation and is felt to be secondary to the direct rupture of alveoli into the pleural space. It can also be a complication of invasive procedures, such as a central venous catheter placement, endotracheal intubation, or feeding tube placement. Blunt chest trauma may result in pneumothorax even in the absence of rib fractures, as a result of a sudden increase in intraalveolar pressure. Following surgical procedures, such as coronary artery bypass and thoracotomy, pneumothorax is commonly encountered and should normally decrease over several days. Spontaneous pneumothorax can also occur with pneumonia, particularly *Pneumocystis* and other cavitary infections, such as *Staphylococcus* and *Klebsiella*.

The majority of air collections in supine patients are located in the basilar anteromedial portion of the hemithorax. Helpful radiographic features indicative of anterobasal pneumothoraces include a lateral or medial deep costophrenic sulcus sign (*Fig. 66-36*); diffuse hyperlucency of the lower hemithorax or the superior upper abdominal quadrant; and diaphragmatic, mediastinal, or cardiac contours that are too sharp compared to their normal appearance (*Table 66-10*).

TABLE 66-10

Pneumothorax on Supine Chest X-Ray

- Lateral or medial deep sulcus sign
- Diffuse hyperlucency of hemithorax or superior upper abdominal quadrant
- Too sharp diaphragmatic, mediastinal, or cardiac contours
- Apicolateral pleural line when upright or semi-upright
- Subcutaneous emphysema

FIGURE 66-36 ■ Anteroposterior (AP) supine chest x-ray. Left medial “deep sulcus sign” (*black arrow*) is consistent with a pneumothorax on a supine chest x-ray. ETT, endotracheal tube, NGT, nasogastric tube, and TT, thoracostomy tube, are in proper good position. Postsurgical sponges/packing (S) are present in both upper abdominal quadrants.

FIGURE 66-37 ■ Anteroposterior (AP) supine chest x-ray. The left hemithorax is hyperexpanded and lucent. Left tension pneumothorax (arrowheads) accounts for these findings as well as deviation of the heart and mediastinum to the right and depression of the ipsilateral hemidiaphragm.

TABLE 66-11

Tension Pneumothorax Characteristics

- Contralateral shift of mediastinum
- Depression of ipsilateral hemidiaphragm
- Flattening of heart border and vena cava (which reflects impairment of normal venous return)

Identification of a pneumothorax on an upright chest film is much easier than on supine films. Typically, there is an apicolateral pleural line with no lung markings beyond it. Decubitus views with the side of interest uppermost can aid in the diagnosis of a pneumothorax. Subcutaneous emphysema along the chest wall or neck should alert one to the presence of occult pneumothorax or pneumomediastinum. CT is much more sensitive for detecting pneumothoraxes, even minute ones, compared with plain radiographs.

Tension pneumothoraces occur when the pressure in the pleural space equals or exceeds the atmospheric pressure and are more common with continuous mechanical ventilation (Fig. 66-37 and Table 66-11).

■ MEDIASTINUM

In critically ill patients, portable supine AP chest radiographs are of limited utility in evaluating the mediastinum. Chest CT is extremely helpful in the mediastinal evaluation because even large mediastinal abnormalities may be hidden on chest radiographs.

FIGURE 66-38 ■ Anteroposterior (AP) supine chest x-ray. Traumatic aortic transection or “tear,” resulting in a wide mediastinum (white arrows) with an indistinct aortic arch (AA), depression of left main stem bronchus (LMB), and deviation of the trachea (T) to the right.

Mediastinal Fluid

Aortic dissection and aortic transection (aortic rupture) are probably the most critical mediastinal abnormalities that need to be ruled out in the acute setting. Mediastinal findings on plain radiographs can include a dense, widened mediastinum (normal mediastinal width at the level of the aortic arch should be <8 cm with supine AP technique); an indistinct aortopulmonary window and descending aortic contour; displaced intimal atherosclerotic calcifications; rightward deviation of the trachea; and downward displacement of the left main stem bronchus (Figs. 66-38 and 66-39). If the acute aortic injury is suspected, a CT aortic angiogram before and after contrast administration should be obtained. On the precontrast images, a hyperdense acute intramural hematoma can be seen. After contrast, findings can include an intimal flap with both true and false lumens in the case of dissections or disruption of the aortic wall with an abrupt change in vessel caliber, pseudoaneurysm, periaortic hematoma, or gross extravasation of contrast material in the case of a transection²¹ (Table 66-12).

The most commonly observed location of traumatic aortic injury is at the aortic isthmus just distal to the left subclavian artery origin. Although the most common location of an aortic transection is at the aortic root, this is rarely seen as this injury is almost always fatal.

With Type I aortic dissections and aortic root transections, hemothorax or pericardial hematomas (Figs. 66-40, A, and 66-40, B) often occur and can result in a cardiac tamponade. With transection at the isthmus, there is usually a left-sided hemothorax with a left apical cap. Mediastinal hematomas in trauma patients can also be due to bleeding from mediastinal veins or sternal or spinal injuries. Esophageal rupture, adenopathy, and mediastinal abscesses after sternotomy can lead to a widened mediastinum.

Mediastinal Gas

In the critically ill patient, the air in the mediastinum is most often secondary to barotrauma. A sudden increase in intralveolar pressure with a rupture directly into the mediastinum rather than the pleural space can also result from blunt trauma, severe coughing, and chronic obstructive pulmonary disease. Other etiologies, such as rupture of the airway or esophagus and infection, can result in pneumomediastinum (Figs. 66-41, A, and 66-41, B). Mediastinal gas can dissect

FIGURE 66-39 ■ Sagittal computed tomography (CT) reconstruction. Acute aortic transection near the level of the ligamentum arteriosum (black arrow).

TABLE 66-12 Acute Aortic Injury

- Dense, widened mediastinum

- Displaced intimal atherosclerotic calcifications
- Rightward deviation of trachea
- Downward displacement at left main stem bronchus
- Left pleural effusion or left apical cap
- Pericardial effusion

superiorly into the neck and subcutaneous tissues or inferiorly into the retroperitoneum.

Pneumomediastinum is detectable on a CXR when air outlines anatomic structures that are not normally visible, such as the medial border of the SVC and great vessels, or surrounds the central pulmonary arteries and thoracic aorta. Due to the continuity of the right and left sides of the mediastinum, air can outline the central portion of the diaphragm under the inferior heart margin.

Pneumopericardium (Fig. 66-42) can be suspected when the air is seen in the superior pericardial recess outlining the great vessels. Pneumomediastinum may lead to pneumopericardium from air tracking along the adventitia of the pulmonary veins and into the pericardial space.³

Upper Abdomen

Abnormalities in the upper abdomen can be seen on chest images. Potentially serious findings include pneumoperitoneum (Fig. 66-43), bowel obstruction, pneumatosis, portal venous gas, and pneumobilia. Unexpected foreign bodies from trauma or surgery (including retained needles or sponges) can also be identified.

FIGURE 66-40 ■ **A**, Axial computed tomography (CT) slice. Large pericardial hematoma (HP) with narrowing of the right ventricle and straightening of the interventricular septum, findings of associated cardiac tamponade. **B**, Axial computed tomography (CT) slice. Etiology of the same patient's hemopericardium (HP) and cardiac tamponade is a "leaking or ruptured" ascending aorta aneurysm (AA).

CONCLUSION

To best serve the critically ill population of patients, integrating available clinical information with a comprehensive systemic analysis of imaging and obtaining appropriate studies are vital. The portable CXR remains the initial study of choice for evaluation of the chest in the ICU. However, CT is used as a problem-solving tool for "hidden" lung abnormalities when plain films are equivocal. Computed tomography provides better anatomic detail and a higher degree of diagnostic accuracy, though is more tedious to obtain in critically ill patients. Ultrasound is also a helpful bedside tool, aiding in the diagnosis of loculated pleural effusions and assisting in the placement of thoracostomy tubes and central lines.

Acute respiratory distress syndrome (ARDS) is a common problem in the intensive care unit and can complicate a wide spectrum of critical illnesses. First described by Ashbaugh in 1967,¹ the syndrome was initially termed the *adult respiratory distress syndrome*, to distinguish it from the respiratory distress syndrome of neonates. However, with the recognition that ARDS can occur in children, the term *acute* has replaced *adult* in the nomenclature in recognition of the typical acute onset that defines the syndrome. Although specific treatments for ARDS have been slow to emerge, new strategies of mechanical ventilation that improve mortality, targeted treatments for severe ARDS that include prone positioning, and neuromuscular paralysis and fluid management strategies that reduce the length of mechanical ventilation emphasize the importance of identifying and treating all patients with ARDS. Although this point would seem to be straightforward, in practice, ARDS remains largely underdiagnosed,^{2,3} and expert practitioners may disagree on the diagnosis⁴ perpetuating inappropriate or inadequate treatment.

■ EPIDEMIOLOGY

The exact incidence of ARDS has been difficult to estimate for a variety of reasons, with estimates ranging from 7 to 85 cases per 100,000 people. In the past, variable definitions of the syndrome were used.⁵ The wide variety of causes and coexisting disease processes has also made identification of cases difficult both at the clinical and administrative coding level.⁶ The National Institutes of Health first estimated the incidence at 75 per 100,000 population in 1977,⁷ while a number of studies since then have reported lower incidences.⁶ Two prospective studies confirmed the higher original National Institutes of Health Estimate. The first used enrollment logs from the National Heart, Lung, and Blood Institute sponsored an ARDS Network of 20 hospitals and estimated that the incidence could be as high as 64 cases per 100,000 population. This dataset has the advantage of being prospectively collected from a large number of academic medical centers. The second was a large, prospective study of residents of King County, Washington. In that study, the crude incidence of ARDS in adults was 78.9 per 100,000 patient years.⁸ A large, prospective European study found that ARDS occurred in 7.1% of all hospital admissions.⁹ Several studies suggest a decline in the incidence of ARDS over time.¹⁰ For example, a large prospective cohort of trauma patients at risk for ARDS and multisystem organ failure collected from 1997 to 2004 showed that the incidence of ARDS decreased from 43% in 1997 to 12% in 2004, a finding that may reflect advances in posttrauma critical care.¹¹ In a population-based study in Olmstead County, Minnesota, the incidence of ARDS declined from 82.4 to 38.9 per 100,000 person-years from 2001 to 2008, despite concurrent increases in severity of acute illness and numbers of comorbidities and a higher prevalence of major predisposing conditions for ARDS.¹² A 1-year observational study in Spain reported an incidence of ARDS of 7.2 per 100,000 population in 2008 and 2009 during the era of routine application of low tidal volume ventilation.¹³ Regardless of the exact incidence, it is clear that ARDS is a major public health problem that will be encountered frequently by all physicians who care for critically ill patients.

■ RISK FACTORS

ARDS almost always occurs in the setting of a predisposing clinical risk factor (Table 67-1), with risk increasing with multiple risk

factors.^{14,15} The commonly associated clinical disorders can be separated into those that directly injure the lung and those that indirectly injure the lung. Although it is not always feasible to determine the exact cause of ARDS in a given patient, direct causes appear to account for approximately one-half of all cases of ARDS.¹⁶ Regardless of the underlying cause of ARDS, most patients with ARDS have a systemic illness with inflammation and organ dysfunction that is not confined to the lung.¹⁷

Sepsis is the most common cause of indirect lung injury, with an overall risk of progression to ARDS of approximately 30% to 40% among patients with severe sepsis requiring intensive care unit (ICU) admission.^{14,18-20} In addition to sepsis itself being a risk factor for ARDS development, the site of infection may also influence the risk of lung injury. In patients admitted to an ICU with sepsis, patients who had pneumonia as the source of sepsis had an increased risk of ARDS compared to those with infections at other sites (abdomen, skin, soft tissue, etc.).²¹ Severe trauma with shock and multiple transfusions also can cause indirect lung injury. Although the other causes of indirect lung injury are less common, many, such as blood transfusions,²² are commonplace events in the ICU setting. The most common cause of direct lung injury is pneumonia, which may be of bacterial, viral, or fungal origin. Secondary factors may also increase the risk. Such factors include chronic lung disease,²⁰ chronic or acute alcohol abuse,^{23,24} cigarette smoking,^{22,25,26} increasing age,²⁷ transfusion of blood products,²⁸⁻³⁰ lung resection,³¹ and obesity.²⁷ By contrast, several studies have shown that patients with diabetes are less likely to develop ARDS.³²⁻³⁴ To some extent, every patient in the ICU is at risk for developing ARDS, and vigilance is required to recognize the diagnosis and treat appropriately.

■ PATHOPHYSIOLOGY

The pathophysiology of ARDS is complex and remains incompletely understood.³⁵ Microscopically, lungs from afflicted individuals in the early stages typically show diffuse alveolar damage with alveolar flooding by proteinaceous fluid, neutrophil influx into the alveolar space, loss of alveolar epithelial cells, deposition of hyaline membranes on the denuded epithelial basement membrane, and formation of microthrombi (Fig. 67-1).³⁶ The alveolar flooding occurs as a result of injury to the alveolar-capillary barrier and is a major determinant of the hypoxemia and altered lung mechanics that characterize early ARDS. The alveolar-capillary barrier is formed of two separate cell layers, the microvascular endothelium, and the alveolar epithelium. Injury to the alveolar epithelium is a prominent feature histologically, with loss of alveolar epithelial barrier integrity and sloughing of alveolar epithelial type I cells. Alveolar epithelial apoptosis is widespread and likely contributes to the loss of epithelium seen ultrastructurally.^{37,38} Although endothelial injury is less obvious at the microscopic level, ultrastructural studies reveal that it is widespread^{39,40} and is accompanied by increased endothelial permeability.³⁵ Endothelial injury allows leakage of plasma from the capillaries into the interstitium and airspaces. The alveolar flooding in ARDS is characteristically with a protein-rich edema fluid due to the increased permeability of the alveolar capillary barrier, in contrast to the low-protein pulmonary edema that results from hydrostatic causes such as congestive heart failure or acute myocardial infarction.⁴¹⁻⁴⁴ Over time, the pathologic changes in ARDS evolve such that acute inflammation and pulmonary edema become less prominent and fibrosing alveolitis may appear. Recent autopsy

TABLE 67-1

Risk Factors Associated with the Development of Acute Respiratory Distress Syndrome

| DIRECT LUNG INJURY | INDIRECT LUNG INJURY |
|------------------------------------|-------------------------------|
| Pneumonia | Sepsis |
| Aspiration of gastric contents | Multiple trauma |
| Pulmonary contusion | Cardiopulmonary bypass |
| Fat, amniotic fluid, or air emboli | Drug overdose |
| Near-drowning | Acute pancreatitis |
| Inhalational injury | Transfusion of blood products |
| Reperfusion pulmonary edema | |

studies show that fibroproliferative changes can be seen even early in ARDS and may coexist with exudative changes.⁴⁵

Neutrophils play an important role in the initial inflammatory response in ARDS.⁴⁶ Early ARDS is characterized by migration of neutrophils into the alveolar compartment.^{39,40} Neutrophils can release a variety of injurious substances including proteases such as neutrophil elastase, collagenase, and gelatinases A and B and reactive nitrogen and oxygen species. In addition, they can elaborate proinflammatory cytokines and chemokines that amplify the inflammatory response in the lung. Recent evidence suggests that neutrophil extracellular traps (NETS) that contain DNA, histones, and other intracellular proteins may act as damage-associated molecular patterns in amplifying the immune response in ARDS.^{47,48} Resident alveolar macrophages are also involved in initiating and sustaining a proinflammatory cytokine cascade that leads to recruitment of neutrophils into the lung.⁴⁹

In addition to acute neutrophilic inflammation and elaboration of a proinflammatory cytokine cascade, a variety of other abnormalities contribute to the pathogenesis of ARDS. Surfactant dysfunction is characteristic, with abnormalities in both the protein and lipid components,⁵⁰⁻⁵³ and likely results from disruption of normal surfactant activity by the influx of plasma proteins into the airspaces, intraalveolar proteolysis, and injury to the alveolar epithelial type II cells. Surfactant dysfunction may have important implications both for lung mechanics and for host defense.⁵⁴ Activation of the coagulation cascade and impaired fibrinolysis are also apparent in patients with ARDS,^{55,56} both in the lung⁵⁷⁻⁵⁹ and systemically.⁶⁰ An alteration in the balance of endogenous oxidants and antioxidants with a fall in endogenous antioxidants⁶¹ despite the increased oxidant production has also been observed.⁶²

The contribution of ventilator-associated lung injury to the pathogenesis of ARDS has been increasingly recognized. There are several mechanisms by which mechanical ventilation can injure the lung. Ventilation at very high volumes and pressures can injure even the normal lung, leading to increased-permeability pulmonary edema due to capillary stress failure⁶³ and sustained elevations of circulating plasma cytokines.⁶⁴ In the injured lung, even tidal volumes that are well tolerated in the normal lung can lead to alveolar overdistension in relatively uninjured areas because the lung available for distribution of the administered tidal volume is greatly reduced and the distribution of inspired gas is uneven.^{65,66} In addition to alveolar overdistension, cyclic opening and closing of atelectatic alveoli can cause lung injury even in the absence of alveolar overdistension. The combination of alveolar overdistension with cyclic opening and closing of alveoli is particularly harmful and can initiate a proinflammatory cytokine cascade.⁶⁷ A ventilatory strategy that was designed to minimize alveolar overdistension and maximize alveolar recruitment ameliorated this proinflammatory cytokine release.⁶⁸ This fundamental insight into the pathogenesis of clinical ARDS has led to multiple clinical trials of novel ventilatory strategies for patients with ARDS, including the landmark ARDS Network trial of 6 mL/kg versus 12 mL/kg tidal volume ventilation⁶⁹ and several trials of higher levels of positive end-expiratory pressure

(PEEP) with or without recruitment maneuvers to maximize alveolar recruitment (see [Treatment](#) section below).

Although current treatment for all patients with ARDS is similar regardless of cause, emerging evidence indicates that there may be biologically and clinically distinct subphenotypes within ARDS that may respond differently to treatment. One such distinction is between patients who develop ARDS as a result of direct injury to the lung (secondary to pneumonia or aspiration) and those who have primarily indirect injury to the lung due to a systemic insult (secondary to sepsis or pancreatitis). Whether the distinction between direct and indirect lung injury is clinically useful is unclear.^{70,71} Some investigators have demonstrated reduced respiratory system compliance in patients with ARDS caused by direct pulmonary injury as compared to that of indirect cause,⁷² although total respiratory system compliance (including the chest wall) is similar.⁷³ Improvement in lung mechanics may be more likely in patients with direct lung injury with the application of PEEP and alveolar recruitment maneuvers.^{74,75} Biomarkers studies suggest that patients with direct lung injury have more evidence of lung epithelial injury, while those with indirect injury have more evidence of endothelial injury.⁷⁶ However, in the largest cohort of patients studied to date, there was no difference in mortality between those with direct (pulmonary) and indirect (extrapulmonary) causes of lung injury.¹⁶

A potentially more clinically useful distinction is between ARDS endotypes derived using statistical approaches. Calfee and colleagues used latent class analysis to discover two distinct ARDS endotypes among patients enrolled in two large clinical trials based on clinical, laboratory, and biomarker measurements.⁷⁷ One group was characterized by high levels of proinflammatory cytokines, higher use of vasopressors, a higher prevalence of sepsis, and lower serum bicarbonate (hyperinflammatory endotype). This group had higher mortality and fewer ventilator- and organ-failure-free days compared to the group that had a more hypoinflammatory endotype. Most interestingly, the same two classes with similar defining features were independently derived from two large, heterogeneous patient cohorts. Identification of biologically and clinically meaningful endotypes has the potential to alter therapeutic approaches to ARDS and will likely be the emphasis of many future studies.

DIAGNOSIS

Clinical Criteria

Several clinical definitions have been used for diagnosis of ARDS since it was first described in 1967. Before 1994, a variety of definitions were used, including the Murray Lung Injury Score.⁷⁸ In 1994, the American European Consensus Conference (AECC) published new clinical definitions for acute lung injury (ALI) and ARDS.⁵ These definitions were recently modified, and the modified version, referred to as the Berlin definition,⁷⁹ is currently the primary diagnostic tool for ARDS for both clinical diagnosis and research purposes ([Fig. 67-2](#)). It differs from the AECC definition in a few important ways. First, the new definition dispenses with the term *acute lung injury* (ALI) and only uses *ARDS*, which is now characterized as either mild, moderate or severe based on the degree of hypoxemia. Second, it specifies that the onset of ARDS, including bilateral infiltrates on chest radiograph, occurs within 1 week of a known precipitant. To meet the definition, patients must be receiving ≥ 5 cm H₂O of continuous positive airway pressure; for mild ARDS, this airway pressure can be delivered by noninvasive positive pressure ventilation. Severity is classified based on the degree of hypoxemia as mild, moderate, or severe. In all patients with suspected ARDS, an underlying cause of acute lung injury (see [Table 67-1](#)) should be sought. In the absence of an identifiable underlying cause, particular attention should be given to the possibility of other causes of pulmonary infiltrates and hypoxemia such as hydrostatic (cardiogenic) pulmonary edema. Finally, the Berlin definition recognizes that elevated vascular filling pressures and ARDS can coexist; there is no absolute requirement in the Berlin definition to rule out a cardiac cause

FIGURE 67-1 ■ Histologic findings in acute respiratory distress syndrome (ARDS). **A** shows a lung-biopsy specimen obtained from a patient 2 days after the onset of the syndrome as a result of the aspiration of gastric contents. Characteristic hyaline membranes are evident (*arrow*), with associated intraalveolar red cells and neutrophils, findings consistent with the pathological diagnosis of diffuse alveolar damage (hematoxylin and eosin, $\times 90$). **B** and **C** show lung biopsy specimens obtained 14 days after the onset of sepsis-associated ARDS. **B** shows granulation tissue in the distal air spaces with a chronic inflammatory-cell infiltrate (hematoxylin and eosin, $\times 60$). Trichrome staining in **C** reveals collagen deposition (*dark blue areas*) in the granulation tissue, a finding consistent with the deposition of extracellular matrix in the alveolar compartment ($\times 60$). **D** shows a specimen of lung tissue from a patient who died 4 days after the onset of ARDS; there is injury to both the capillary endothelium and the alveolar epithelium. An intravascular neutrophil (LC) can be seen in the capillary (C). Vacuolization and swelling of the endothelium (EN) are apparent. Loss of alveolar epithelial cells is also apparent, with the formation of hyaline membranes on the epithelial side of the basement membrane (BM*). **E** shows a specimen of lung tissue obtained from a patient during the fibrosing-alveolitis phase in which there is evidence of reepithelialization of the epithelial barrier with alveolar epithelial type II cells. The arrow indicates a typical type II cell with microvilli and lamellar bodies containing surfactant. The epithelial cell immediately adjacent to this cell is in the process of changing to a type I cell, with flattening, loss of lamellar bodies, and microvilli. The interstitium is thickened, with deposition of collagen (C). (Permission from Ware LB, Matthay MA. Medical progress: the acute respiratory distress syndrome. *N Engl J Med*. 2000;342:1334-49.)

of pulmonary edema unless a patient's respiratory failure cannot be explained fully by an ARDS risk factor. In these instances, objective cardiac testing such as echocardiography or pulmonary artery catheterization can be used.

One potential limitation of the Berlin definition is the need for arterial blood gas sampling to calculate a $\text{PaO}_2/\text{FiO}_2$ ratio. Recent work

has shown good correlation between the $\text{SpO}_2/\text{FiO}_2$ ratio (measured by pulse oximetry) and the $\text{PaO}_2/\text{FiO}_2$ ratio,^{80,81} with an $\text{SpO}_2/\text{FiO}_2$ ratio of 235 corresponding to a $\text{PaO}_2/\text{FiO}_2$ ratio of 200 and an $\text{SpO}_2/\text{FiO}_2$ ratio of 315 correlating to a $\text{PaO}_2/\text{FiO}_2$ ratio of 300. These correlations are valid only when the SpO_2 is less than 98% because the oxyhemoglobin dissociation curve is flat above this level. As measurement of oxygen

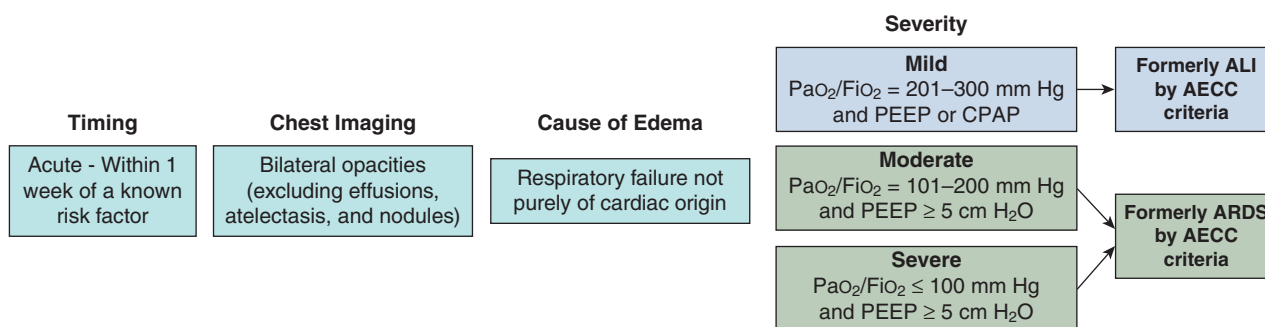

FIGURE 67-2 ■ The Berlin Definition of ARDS.

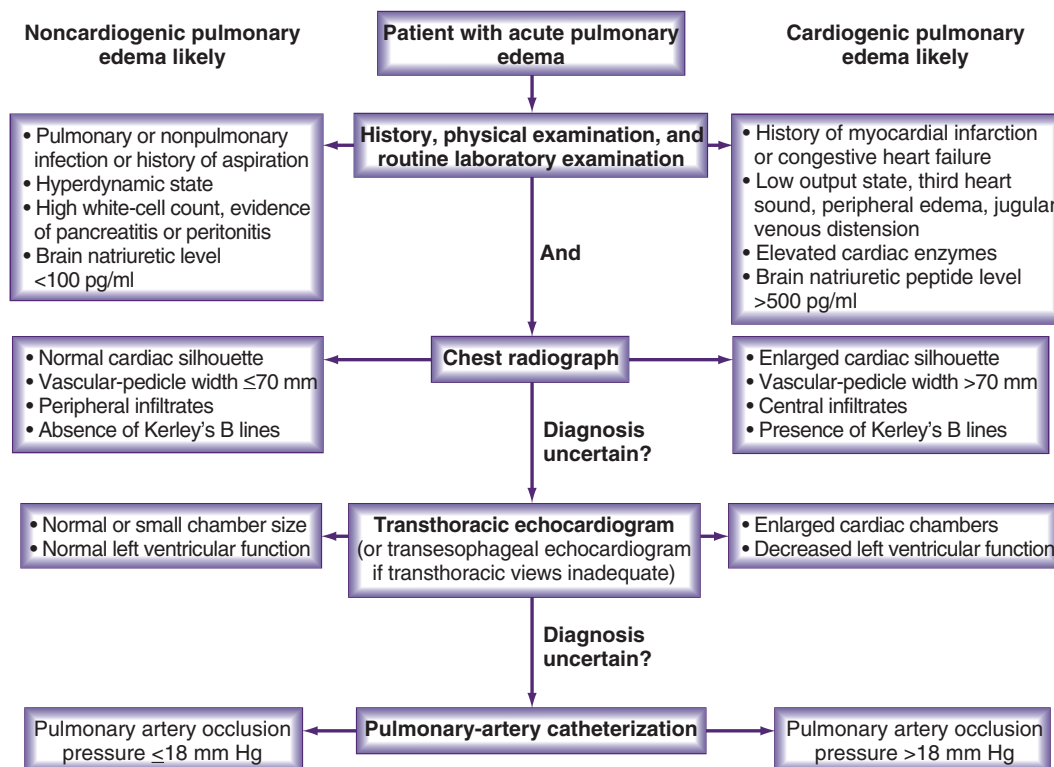

FIGURE 67-3 ■ Algorithm for differentiating between cardiogenic and noncardiogenic pulmonary edema. (With permission from Ware LB, Matthay MA. Clinical practice. Acute pulmonary edema. N Engl J Med. 2005;353[26]:2788-2796.)

saturation is noninvasive, continuous measurements and the use of the SpO₂/FiO₂ ratio in addition to the PaO₂/FiO₂ ratio may improve the ability of clinicians to diagnose ARDS.⁸² However, the SpO₂ has yet to be incorporated into formal definitions of ARDS.

Differentiation between ARDS and hydrostatic edema can be difficult, and there may be significant overlap in these syndromes (Fig. 67-3).⁸³ A multicenter trial of intravenous catheter directed fluid management strategies in patients with ARDS showed that 29% of those with clinically defined ARDS had a PAOP >18 mm Hg at the time of pulmonary artery catheter insertion but that 97% had a normal or elevated cardiac index, suggesting that they did not have clinical heart failure.⁸⁴ Other studies have shown similar rates of elevated PAOP in patients with ARDS.⁸⁵ There are no specific clinical or laboratory studies that can reliably distinguish between ARDS and hydrostatic edema. A study examining the diagnostic utility of serum levels of

B-type natriuretic peptide (BNP) showed that BNP measured at admission could not reliably differentiate between hydrostatic edema and ARDS. Furthermore, BNP levels in these patients did not correlate with invasive hemodynamic measurements.⁸⁶ N-terminal BNP levels are also elevated in ARDS⁸⁷ but do not necessarily correlate with PAOP.

Although the standardization of ARDS definitions has been of enormous value for both clinical diagnosis and clinical research, the nature of ARDS is such that any definition will have shortcomings. First, the Berlin definition is based solely on clinical criteria because currently there is no laboratory test that allows clinical assessment of the presence or absence of ARDS. Second, the presence or absence of multiorgan dysfunction, an important determinant of outcome, is not specified. Finally, although the presence of bilateral infiltrates has major prognostic significance and is clearly a hallmark of the syndrome, the radiographic findings are not specific for ARDS,^{4,88} and a

TABLE 67-2 Ventilator Management of Patients with ARDS**CALCULATE PREDICTED BODY WEIGHT (PBW)**

- Males: PBW (kg) = $50 + 2.3 [(height \text{ in inches}) - 60]$ or $50 + 0.91 [(height \text{ in cm}) - 152.4]$
- Females: IBW (kg) = $45.5 + 2.3 [(height \text{ in inches}) - 60]$ or $45.5 + 0.91 [(height \text{ in cm}) - 152.4]$

VENTILATOR MODE

Volume Assist/Control until weaning

TIDAL VOLUME (VT)

- Initial Vt: 6 mL/kg predicted body weight
- Measure inspiratory plateau pressure (Pplat, 0.5 sec inspiratory pause) every 4 hours AND after each change in PEEP or Vt.
- If Pplat > 30 cm H₂O, decrease Vt to 5 or to 4 mL/kg.
- If Pplat < 25 cm H₂O and Vt < 6 mL/kg PBW

RESPIRATORY RATE (RR)

- With initial change in Vt, adjust RR to maintain minute ventilation.
- Make subsequent adjustments to RR to maintain pH 7.30-7.45, but do not exceed RR = 35/min and do not increase set rate if PaCO₂ < 25 mm Hg.

I : E Ratio

Acceptable range, 1:1-1:3 (no inverse ratio)

FiO₂, PEEP, AND ARTERIAL OXYGENATION

Maintain PaO₂ = 55-80 mm Hg or SpO₂ = 88%-95% using the following PEEP/FiO₂ combinations:

| FiO ₂ | 0.3-0.4 | 0.4 | 0.5 | 0.6 | 0.7 | 0.8 | 0.9 | 1 |
|------------------|---------|------|------|-------|-------|-------|-------|-------|
| PEEP | 5-8 | 8-14 | 8-16 | 10-20 | 10-20 | 14-22 | 16-22 | 18-25 |

ACIDOSIS MANAGEMENT

- If pH < 7.30, increase RR until pH ≥ 7.30 or RR = 35/min.
- If pH remains < 7.30 with RR = 35, consider bicarbonate infusion.
- If pH < 7.15, Vt may be increased (Pplat may exceed 30 cm H₂O).

ALKALOSIS MANAGEMENT

If pH > 7.45 and patient not triggering ventilator, decrease set RR but not below 6/min.

FLUID MANAGEMENT

- Once patients are out of shock adopt a conservative fluid management strategy.
- Use diuretics or fluids to target a central venous pressure (CVP) of <4 or a pulmonary artery occlusion pressure (PAOP) of <8.

LIBERATION FROM MECHANICAL VENTILATION

- Daily interruption of sedation
- Daily screen for spontaneous breathing trial (SBT)
- SBT when all of the following criteria are present:
 - (a) FiO₂ < 0.40 and PEEP < 8 cm H₂O
 - (b) Not receiving neuromuscular blocking agents
 - (c) Patient is awake and following commands.
 - (d) Systolic arterial pressure > 90 mm Hg without vasopressor support
 - (e) Tracheal secretions are minimal, and the patient has a good cough and gag reflex.

SPONTANEOUS BREATHING TRIAL

- Place patient on 5 mm Hg pressure support with 5 mm Hg PEEP or T-piece.
- Monitor HR, RR, oxygen saturation for 30-90 minutes.
- Extubate if there are no signs of distress (tachycardia, tachypnea, agitation, hypoxia, diaphoresis).

variety of other conditions can mimic ARDS (Table 67-2).⁸⁹ For these reasons, diagnostic uncertainty in ARDS is common,⁹⁰ is a major barrier to initiation of appropriate therapy, and is one of the main reasons why clinicians fail to initiate lung protective ventilation in clinically appropriate patients.⁹¹

Invasive Methods

In the majority of patients, the initial diagnosis of ARDS is made clinically. Invasive procedures for diagnosis of ARDS are of limited clinical utility and the benefits often do not outweigh the risks.⁹² Among the potential invasive diagnostic methods available, bronchoscopy is the most frequently used. Bronchoscopy may be indicated in the early phases of ARDS in patients for whom there is no identifiable predisposing risk factor and in the immunosuppressed. Bronchoalveolar lavage for cultures and cytologic examination can identify the cause of pneumonia and is particularly useful in the diagnosis of opportunistic infections. Lavage fluid usually has a predominance of neutrophils, and there may be evidence of diffuse alveolar hemorrhage. Cytologic

examination can be used to confirm the presence of diffuse alveolar damage.⁹³ Rarely an alternate, treatable diagnosis is found such as acute eosinophilic pneumonia, pulmonary alveolar proteinosis, diffuse alveolar hemorrhage, or unsuspected infection.

In the past, open lung biopsy was obtained more frequently for diagnosis. Interestingly, the degree of histologic abnormality on lung biopsy does not correlate with ultimate outcome as measured by pulmonary function.⁹⁴ Open or thoracoscopic lung biopsy may still be useful in some cases where the diagnosis is uncertain and the underlying cause is not apparent. Although open lung biopsy can provide findings that lead to a change in treatment, a meta-analysis of published series indicated that postoperative complications occurred in 22% of patients.⁹⁵ Several pathologic studies have shown that biopsy or autopsy can identify unsuspected diagnoses requiring specific therapy such as miliary tuberculosis, pulmonary blastomycosis, aspergillosis, or bronchiolitis obliterans organizing pneumonia in 40% to 60% of cases⁹⁶⁻⁹⁸; however, the general applicability of these studies may be limited by the fact that they were retrospective case series. In a meta-analysis of published studies, open lung biopsy altered management in

73% of cases⁹⁵; biopsy findings that alter management may be associated with better survival.⁹⁹

In addition to familiarity with the Berlin definition of ARDS, the critical care clinician should be aware that ARDS also has been called by a variety of other terms, some of which are seen mainly in older literature but some that remain in clinical use. Some of the more common of these terms include adult hyaline membrane disease, post-perfusion lung or pump lung, shock lung, ventilator-associated lung injury, and adult respiratory insufficiency syndrome. The terms *reperfusion pulmonary edema*, *primary graft dysfunction*, *primary graft failure*, and *transplant lung* have been used to describe ARDS occurring immediately after lung transplantation. Regardless of the name applied, ARDS is a clinical syndrome that has prognostic and therapeutic implications above and apart from the underlying cause (i.e., infections, aspiration, trauma, etc.). This fact does not diminish the imperative to identify these underlying causes, if present, and treat them aggressively.

CLINICAL COURSE

Early ARDS

The Berlin definition aims to identify ARDS patients early in their course, in the acute or exudative phase. Clinically, the acute phase is manifested by the acute onset of radiographic infiltrates consistent with pulmonary edema, hypoxemia, and increased work of breathing. Radiographic infiltrates are bilateral (by definition) but may be patchy or diffuse, fluffy or dense (Fig. 67-4), and pleural effusions may occur.¹⁰⁰ Chest computed tomographic (CT) imaging, though rarely used clinically, has been employed extensively as an investigative tool to better define the nature of the radiographic infiltrates in patients with ARDS. The distribution of infiltrates by CT is surprisingly variable. Although some patients have evidence of diffuse alveolar edema on CT, many patients have more focal infiltrates with areas of alveolar filling and consolidation occurring predominantly in dependent zones, while nondependent regions are relatively spared.¹⁰¹⁻¹⁰³ However, even areas that appear spared in conventional radiographic images may have substantial inflammation when sampled using bronchoalveolar lavage¹⁰⁴ or imaged using FDG-PET.¹⁰⁵ Patients with more diffuse infiltrates may be more likely to respond to recruitment maneuvers¹⁰⁶; whether CT imaging could be helpful for guiding ventilator treatment is not yet known.

The hypoxemia that characterizes early ARDS is usually relatively refractory to supplemental oxygen. The increased work of breathing in the acute phase of ARDS is due to decreased lung compliance as a result of alveolar and interstitial edema combined with increased

FIGURE 67-4 ■ Representative chest radiograph from a patient with acute respiratory distress syndrome.

airflow resistance¹⁰⁷ and increased respiratory drive.¹⁰⁸ The combination of hypoxemia and increased work of breathing usually necessitates endotracheal intubation and mechanical ventilation, although occasionally patients can be managed with noninvasive ventilation or very high-flow nasal cannula oxygen (see [Treatment](#) section below).

In addition to hypoxemia and increased work of breathing, many patients with ARDS also develop evidence of increased pulmonary vascular resistance, leading to pulmonary hypertension and acute right ventricular (RV) failure. The prevalence of pulmonary hypertension in patients presenting to the hospital with ARDS may be as high as 92%.¹⁰⁹ Even in the era of low tidal volume ventilation, transesophageal echocardiography showed evidence of acute right ventricular failure in 22% of 226 consecutive patients with moderate or severe ARDS¹¹⁰ that was associated with an almost two-fold increase in 28-day mortality. Attempts to reverse pulmonary hypertension and RV failure with pulmonary vasodilators such as sildenafil have led to decreased pulmonary artery pressure with treatment as well as concomitant increases in shunt fraction and decreases in oxygenation.¹¹¹ These findings suggest that although patients with ARDS have evidence of pulmonary hypertension, it may, in some cases, be a beneficial physiologic response to reduce blood flow to areas of severely compromised lung.

Late Fibroproliferative ARDS

In most patients, ARDS will substantially resolve after the acute phase. However, in others, the syndrome progresses to a fibrosing alveolitis. Fibrosing alveolitis usually becomes clinically apparent after 7-10 days, although evidence of deposition of extracellular matrix has been identified in alveolar lining fluid from patients as early as the first day after intubation,¹¹² and autopsy studies show early fibrotic changes in some patients.⁴⁵ Radiographically, linear opacities develop, consistent with the evolving fibrosis. Histologically, pulmonary edema and neutrophilic inflammation are less prominent. A severe fibroproliferative process fills the airspaces with granulation tissue that contains extracellular matrix rich in collagen and fibrin as well as new blood vessels and proliferating mesenchymal cells.^{113,114}

Clinically, the late fibroproliferative phase of ARDS is characterized by continued need for mechanical ventilation, often with persistently high levels of PEEP and FiO_2 . The lung compliance may fall even further, and pulmonary dead space is elevated. If it has not developed in the acute phase, pulmonary hypertension may develop now due to obliteration of the pulmonary capillary bed, and right ventricular failure may occur.¹¹⁵ This phase of the illness can be prolonged, lasting weeks, and can be very frustrating for the clinician, patient, and family, as small gains in pulmonary function are frequently offset by new problems such as hospital-acquired infections and nonpulmonary organ dysfunction. Progressive deconditioning can make eventual weaning from mechanical ventilation difficult if the fibrosing alveolitis stage is prolonged. Based on the improvement in the number of ventilator-free days through use of lower tidal volumes, it seems likely that the incidence of fibrosing alveolitis is falling. However, a recent autopsy study found more fibrotic changes in patients treated in the low tidal volume era than in patients treated with higher tidal volumes.⁴⁵ One possible explanation is that better supportive care has prolonged survival of some patients with more severe lung injury, allowing more time for fibrotic changes to develop and be detected at autopsy.

Resolution of ARDS

Lung biopsies from ARDS survivors typically show normal or near-normal lung histology. For such histologically complete resolution of ARDS to occur, a variety of processes must be reversed. Alveolar edema is actively reabsorbed by the vectorial transport of sodium and chloride from the distal airway and alveolar spaces into the lung interstitium where it can be cleared by the lymphatics or by reabsorption into the vasculature.¹¹⁶ Water is passively absorbed along the osmotic gradient, probably through water channels, the aquaporins.¹¹⁷ The majority of patients with early ARDS have impaired alveolar fluid

transport; in those with intact alveolar fluid transport, faster rates of alveolar epithelial fluid transport are associated with better outcomes.⁴¹ Soluble and insoluble protein must also be cleared from the airspaces. Soluble protein probably diffuses by a paracellular route into the interstitium, where it is cleared by lymphatics. Insoluble protein probably is cleared by macrophage phagocytosis or alveolar epithelial cell endocytosis and transcytosis.¹¹⁸

The denuded alveolar epithelium must be repaired. The alveolar epithelial type II cell serves as the progenitor cell for repopulating the alveolar epithelium. Type II cells proliferate, migrate, and differentiate to reconstitute a tight alveolar epithelial type I cell barrier. The inflammatory cell infiltrate must also resolve, but here the mechanisms are less clear. Resolution of neutrophilic inflammation may be predominantly via neutrophil apoptosis and phagocytosis by macrophages. However, one report suggests that neutrophil apoptosis is impaired in the lungs of patients with ARDS.¹¹⁹ The resolution of fibrotic changes is also not well understood. Clearly, substantial remodeling is necessary to restore a normal or near-normal alveolar architecture. In patients with advanced fibrosis, this process likely takes place over many months, as pulmonary function abnormalities continue to improve, sometimes remarkably so, out to the first year and beyond in survivors of ARDS (see below).^{120,121}

TREATMENT

Standard Supportive Therapy

The gradual decline in mortality attributable to ARDS over time^{122,123} likely reflects improvements in standard supportive therapy. Although detailed discussion of all aspects of supportive therapy is beyond the scope of this chapter, a few aspects will be considered.

Treatment of Predisposing Factors

First and foremost, a search for the underlying cause of ARDS should be undertaken. Appropriate treatment for any precipitating infection such as pneumonia or sepsis is critical to enhance the chance of survival. In the immunocompromised host, invasive diagnostic evaluation, including bronchoscopy, may be warranted to look for evidence of opportunistic infections. In a patient with sepsis and ARDS of unknown source, an intraabdominal process should be considered. Timely surgical management of intraabdominal sepsis is associated with better outcomes.¹²⁴ In some patients, the cause of lung injury will not be specifically treatable (such as aspiration of gastric contents) or will not be readily identifiable.

Fluid and Hemodynamic Management

Historically, patients with critical illness and ARDS received a pulmonary artery catheter (PAC) to manage fluid and hemodynamic status. A large, randomized European trial of PAC use compared to no PAC use in all patients admitted with ARDS¹²⁵ showed no difference in clinical outcomes on either group, suggesting that routine PAC use in ARDS without specified PAC-guided interventions is not beneficial. The ARDS Clinical Trials Network tested the value of pulmonary artery catheterization in the context of specific fluid management protocols and was unable to demonstrate the superiority of PAC over the central venous catheter in directing specific fluid management protocols in ARDS patients, and PAC use did not improve outcomes in these patients.⁸⁴ Some investigators have proposed that clinical outcomes in ARDS can be improved by delivery of supranormal levels of oxygen using vigorous volume resuscitation and positive inotropes. However, no benefit to supranormal levels of oxygen delivery has been demonstrated in patients with ARDS.^{126,127}

For decades there was disagreement as to the best fluid management strategy in patients with ARDS. Proponents of a liberal fluid strategy reasoned that increased circulating volume would preserve end organ perfusion and protect patients from the development of

nonpulmonary organ failures. Reductions in intravascular volume can have adverse effects on cardiac output and tissue perfusion, factors that could contribute to multisystem organ failure. This concern is legitimate, since mortality in ARDS is usually from nonpulmonary causes including other organ failures. Others support a conservative fluid strategy in an attempt to reduce circulating volume, thereby reducing the driving force for pulmonary edema formation. In experimental lung injury, lower left atrial pressures are associated with less formation of pulmonary edema.^{128,129} Some limited clinical evidence supports this approach.¹³⁰⁻¹³³ Because of this equipoise, the ARDS Network conducted a large, multicenter, randomized controlled trial of catheter (central venous catheter vs. pulmonary artery catheter)—driven fluid management in patients with ARDS.⁸⁴ Once patients were out of shock they were randomized to a liberal fluid treatment strategy that resulted in an average of 1 L of fluid accumulation per day or to a conservative fluid treatment strategy with aggressive use of diuretics to achieve a goal CVP <4 or a goal PAOP <8, resulting in an average of zero net fluid accumulation by day 7. Although there was no difference in mortality at 60 days (the primary outcome of the study), patients in the conservative group had improved oxygenation and significantly more ventilator-free days without the development of additional organ failures. In this study it did not matter whether treatment was guided by central venous pressure measurements (derived from a central venous line) or from pulmonary arterial occlusion pressure measurements (derived from a pulmonary artery catheter).¹³⁴

Despite the findings in support of a conservative fluid management strategy in patients with ARDS, there continues to be a great deal of uncertainty about the appropriate goals for hemodynamic therapy in ARDS. Currently, the recommended strategy is to aim to achieve the lowest intravascular volume that maintains adequate tissue perfusion as measured by urine output, other organ perfusion, and metabolic acid-base status using central venous pressure monitoring to direct therapy. If organ perfusion cannot be maintained in the setting of adequate intravascular volume, then administration of vasopressors and/or inotropes should be used to restore end organ perfusion.¹¹⁵ Available evidence does not support the use of one particular vasopressor or combination of vasopressors. Once shock has resolved, patients should be managed with a conservative fluid strategy with the goal of driving the CVP <4 to keep each patient's fluid balance net zero during the ICU stay.

Nutrition

Standard supportive care for the patient with ARDS includes the provision of adequate nutrition. The enteral route is preferred to the parenteral route and is associated with less infectious complications.¹³⁵ Enteral feeding may also have other beneficial effects. Experimentally, lack of enteral feeding promoted translocation of bacteria from the intestine.¹³⁶ In normal volunteers, administration of parenteral nutrition with bowel rest increased circulating levels of TNF- α , glucagon and epinephrine, and increased febrile responses compared to volunteers who received enteral nutrition.¹³⁷

The goals of nutritional support in any critically ill patient include the provision of adequate nutrients for the patient's level of metabolism and the treatment and prevention of any deficiencies in micro- or macronutrients.¹³⁸ Whether a particular dietary composition could be beneficial in patients with ARDS is unclear. Immunomodulation via dietary manipulation has been attempted by a number of investigators in critically ill patients using various combinations of omega-3 fatty acids, ribonucleotides, arginine, and glutamine. A meta-analysis of these trials suggested a beneficial effect on infection rate but not overall mortality.¹³⁹ However, a large, multicenter, randomized placebo-controlled study of omega-3 fatty acid and antioxidant supplementation in patients with ARDS was stopped early by the data safety monitoring board for a trend towards excess mortality in patients receiving the omega-3 fatty acid supplement.¹⁴⁰ Using a different approach, a high-fat, low-carbohydrate diet reduced the duration of mechanical ventilation in patients with acute respiratory failure.¹⁴¹

Although the mechanism of this beneficial effect was postulated to be due to reduction of the respiratory quotient and a resultant fall in carbon dioxide production, the most common cause of a high respiratory quotient in critically ill patients is not dietary composition but simply overfeeding.¹³⁸ A study of clinical outcomes in 1000 ARDS patients randomized to full calorie versus trophic (10 cc/hr) enteral feeds did not show any difference in mortality or other clinical outcomes.¹⁴² Overall, there is still no compelling evidence to support the use of anything other than standard (enteral) nutritional support, with avoidance of overfeeding, in patients with ARDS. How early to attempt institution of feeding remains an unanswered question.

Mechanical Ventilation

Lung Protective Ventilation

Although historically a tidal volume of 12 to 15 mL per kg was recommended in patients with ARDS, it is now clear that a low-tidal volume, plateau pressure-limited ventilatory strategy reduces mortality. In 2000, the NIH ARDS Network published the findings of their first randomized, controlled, multicenter clinical trial in 861 patients.⁶⁹ The trial was designed to compare a lower tidal volume ventilatory strategy (6 mL/kg predicted body weight, plateau pressure < 30 cm H₂O) with a higher tidal volume (12 mL/kg predicted body weight, plateau pressure < 50 cm H₂O). The rationale for the clinical trial was the growing body of clinical and experimental evidence suggesting that ventilation with high tidal volumes and high plateau pressures might be harmful to the injured lung (see [Pathophysiology](#) section above). In this trial, the inhospital mortality rate was 40% in the 12-mL/kg group and 31% in the 6-mL/kg group, a 22% reduction. Ventilator-free days and organ failure-free days were also significantly improved in the low-tidal volume group. These findings were truly remarkable, since no prior large randomized clinical trial of any specific therapy for ARDS had ever demonstrated a mortality benefit.

The current recommended treatment strategy for patients with ARDS is summarized in [Table 67-3](#). Predicted body weight is calculated based on measured height using the equations provided. This is a key point that is often overlooked by clinicians; use of actual rather than predicted body weight can result in the use of erroneously high

and potentially injurious tidal volumes, particularly if obesity is present. The tidal volume should initially be set at 6 mL/kg predicted body weight. Interestingly, a tidal volume of 6 mL/kg predicted body weight is similar to normal tidal volumes in spontaneously breathing adults at rest. So, although this particular tidal volume is often referred to as low tidal volume, it is really *normal* tidal volume ventilation. However, if the end-inspiratory plateau pressure (measured during a 0.5-second pause) is still >30 cm H₂O, then the tidal volume must be reduced in a stepwise fashion by 1 mL/kg to a minimum of 4 mL/kg. Ventilation with this tidal volume is generally well tolerated. Some patients may have breath stacking or significant dyssynchrony with the ventilator. Increasing the inspiratory flow rate, and if necessary, the level of sedation, is usually sufficient to manage these problems. Several studies have shown that, on average, patients receiving lower tidal volume ventilation do not require increases in dose or duration of sedatives compared to patients receiving higher tidal volume ventilation.^{143,144} Respiratory acidosis may develop but is usually not symptomatic. Raising the respiratory rate is usually sufficient to compensate for the decreased tidal volume; a rate as high as 35 was used in the clinical trial. As with any mode of ventilation in ARDS, patients occasionally will require neuromuscular blockade to alleviate severe dyssynchrony. Although many believe that neuromuscular blockade should be reserved for patients with severe hypoxemia, since the use of paralytics may increase the risk of critical illness polyneuropathy and myopathy, one randomized clinical trial showed a 28-day mortality benefit with use of neuromuscular paralysis with cisatracurium besylate for the first 48 hours in severe ARDS ($\text{PaO}_2/\text{FiO}_2 < 150$).¹⁴⁵

In the ARDS Network protocol, the level of PEEP and FiO_2 is titrated according to a set of predetermined values (see [Table 67-3](#)). The optimal level of PEEP in ARDS has been controversial. Higher levels of PEEP may be beneficial in preventing alveolar collapse and minimizing injurious repeated opening and closing of alveoli. On the other hand, higher PEEP may overdistend and injure more compliant areas of the lung. Several studies have investigated the effects of different levels of PEEP in patients with ARDS.¹⁴⁶ One large multicenter trial conducted by the ARDS Network randomized patients with ARDS ventilated with low-tidal volume ventilation to receive lower (mean PEEP levels on days 1-4 were 8.3 ± 3.2) versus higher levels of PEEP (mean PEEP levels on days 1-4 were 13.2 ± 3.5).¹⁴⁷ In this study there were no differences between the groups in clinical outcomes including ventilator-free days and mortality. Two other studies of the effects of PEEP in ARDS had similar results,^{148,149} although one of the studies did show an increase in the number of ventilator-free days and organ failure-free days with application of higher PEEP.¹⁴⁹ None of these trials has shown significant increases in barotrauma related to higher PEEP levels. Although these three, large studies have not shown beneficial effects of higher PEEP in all patients with ARDS, there may be a subset of patients who would benefit from higher PEEP. In a small trial, a ventilator strategy that incorporated low tidal volume and titration of the PEEP level to above the lower inflection point on each individual patient's pressure volume curve improved mortality in ARDS.¹⁵⁰ However, measurement of the pressure volume curve in any given patient is not practical clinically. Given the lack of compelling data favoring either a high PEEP or low PEEP strategy, current recommendations are to adjust the PEEP within an acceptable range (see [Table 67-3](#)) to achieve adequate oxygenation at a given FiO_2 .

Prone positioning was initially studied in several small¹⁵¹⁻¹⁵³ and three large trials¹⁵⁴⁻¹⁵⁶ and was associated with improvements in oxygenation but no reduction in mortality. Subgroup analysis suggested potential benefit in severe ARDS, leading to a multicenter prospective randomized trial of prolonged prone position (>16 h/day) in patients with severe ARDS ($\text{PaO}_2/\text{FiO}_2 < 150$) that showed a substantial reduction in 28-day mortality in the prone group.¹⁵⁷ Given the results of this trial, prone positioning should be considered in all patients with severe ARDS who do not have contraindications to prone positioning such as elevated intracranial pressure, severe hemoptysis, recent sternal surgery, pregnancy, new deep venous thrombosis or unstable fractures.

TABLE 67-3 Conditions That Mimic ARDS

| | FINDINGS ON CHEST IMAGING | POTENTIAL DIAGNOSTIC TESTS |
|---|---|--|
| Diffuse alveolar hemorrhage | Bilateral alveolar and ground glass infiltrates | Bronchoscopy with bronchoalveolar lavage |
| Pulmonary alveolar proteinosis | Central and lower lung zone alveolar infiltrates, "bat wing" appearance, "crazy paving" on CT | High-resolution computed tomography, bronchoscopy with bronchoalveolar lavage and PAS staining |
| Acute interstitial pneumonia | Bilateral alveolar and ground glass infiltrates, septal thickening, traction bronchiectasis | No alternative cause of ARDS identified, open or thoracoscopic lung biopsy |
| Cryptogenic organizing pneumonia | Peripheral distribution of alveolar infiltrates, migratory infiltrates | Bronchoscopy with transbronchial lung biopsy |
| Acute exacerbation of idiopathic pulmonary fibrosis | Ground glass opacities superimposed on peripheral, basilar fibrotic changes | Computed tomography demonstrating characteristic fibrotic changes |

Noninvasive Ventilation and High-Flow Nasal Cannula

Noninvasive positive pressure ventilation (NIV) delivered by nasal or full face mask has been highly successful in avoidance of intubation in patients with acute exacerbation of COPD.¹⁵⁸ Noninvasive ventilation is commonly used in pediatric patients with ARDS,¹⁵⁹ although there is only one, small randomized trial of 50 patients showing that NIV improved oxygenation and prevented the need for endotracheal intubation in children admitted with acute respiratory failure. The role for NIV in adults with ARDS is still unclear. A growing number of small studies suggest that bilevel NIV with pressure support ventilation and PEEP may reduce the need for intubation and improve outcomes in selected patients with ARDS.^{160,161} However, data from large, randomized controlled trials is still lacking. Furthermore, it seems likely that the majority of patients with ARDS will still require invasive mechanical ventilation. In one large multicenter study of 354 of 2770 patients with acute hypoxemic respiratory failure *who were not already intubated*, NIV failed in 30% of patients but failed in 51% of patients with ARDS.¹⁶² One group of patients in whom NIV is particularly appealing is those patients who are immunosuppressed for various reasons and are at highest risk for nosocomial infections. Encouraging results have now been reported in a variety of patients with acute respiratory failure and immunosuppression.¹⁶³⁻¹⁶⁵

More recently, very high-flow nasal cannulas oxygen delivery has been tested in patients with acute hypoxemic respiratory failure as an alternative to immediate intubation. In a study of 310 patients with acute respiratory failure including some patients with ARDS, treatment with high-flow nasal cannula increased ventilator-free days and reduced mortality compared to noninvasive or invasive mechanical ventilation.¹⁶⁶ One benefit of high-flow nasal cannula is that it can provide a significant level of PEEP noninvasively. Pending data from larger randomized clinical studies, a trial of noninvasive mechanical ventilation or high-flow nasal cannula oxygen could be considered in a patient with ARDS who does not have a severe oxygenation defect, hemodynamic instability, or altered mental status as long as the patient can be closely observed and readily intubated if needed.

Pharmacologic Therapy

There is no specific pharmacologic therapy for ARDS. A variety of treatment strategies have been investigated in large randomized trials including antiinflammatory strategies, surfactant replacement, vasodilation, novel anticoagulants, antioxidants, and strategies to enhance the resolution of pulmonary edema. Agents that appeared promising in experimental and early clinical studies but failed in large randomized trials include early glucocorticoids,^{167,168} anti-TNF antibody fragments,¹⁶⁹ alprostadil,¹⁷⁰⁻¹⁷² surfactant,¹⁷³⁻¹⁷⁵ ketoconazole,¹⁷⁶ N-acetylcysteine,¹⁷⁷ procysteine,¹⁷⁷ lisofylline,¹⁷⁸ statins,¹⁷⁹ albuterol,^{180,181} recombinant activated protein C,¹⁸² and site-inactivated recombinant factor VIIa.¹⁸³

Some investigators have suggested that glucocorticoid therapy, although not helpful for the acute phase of ARDS, might hasten the resolution of late fibroproliferative ARDS. One very small randomized study (plagued by crossovers such that only 4 patients remained in the placebo arm) suggested that glucocorticoid therapy might be beneficial in late ARDS.¹⁸⁴ This question was addressed in a randomized, multicenter study conducted by the ARDS Network of 14 days of methylprednisolone in patients who had persistent ARDS for 7 days.¹⁸⁵ Compared to patients treated with placebo, those treated with methylprednisolone had an increase in the number of shock-free days and ventilator-free days by day 28 as well as improvements in oxygenation but did not have improved survival and had higher rates of reintubation perhaps due to neuromuscular weakness. Given the serious concern about the safety of high-dose glucocorticoids in critically ill patients, including the possibility of increasing the risk of nosocomial infections or critical illness polyneuropathy/myopathy and the lack of improvement in mortality, routine use of glucocorticoids cannot be recommended.

Despite the dismal findings of the numerous studies of pharmacologic therapy for ARDS to date, new therapeutic strategies are under investigation and may yet be beneficial. Because of the failure of pharmacologic therapies in established ARDS, attention has turned to the prevention and early treatment of ARDS, and several trials are in the planning stages or ongoing. For established ARDS, cell-based therapy with intravenous mesenchymal stromal (stem) cells (MSCs) is currently being tested in a phase 2 clinical trial. In preclinical studies, MSCs have pleiotropic protective and reparative effects in the lung including secretion of antiinflammatory and antibacterial factors, secretion of epithelial and endothelial growth factors, and direct transfer of mitochondria to restore energy balance in the injured lung epithelium.¹⁸⁶ Another area under active investigation includes strategies to hasten or facilitate the resolution of ARDS. Such therapies might be targeted at increasing the rate of alveolar fluid clearance, modulating alveolar epithelial repair, or modulating immune regulation of the resolution of inflammation.

Rescue Therapies

Despite appropriate treatment, a fraction of patients with ARDS will have profound and refractory hypoxemia. The initial management of these patients includes increased sedation and neuromuscular paralysis to maintain adequate oxygenation. In patients who do not respond to conventional treatment with low-tidal volume ventilation and remain persistently hypoxemic, there are several nonproven rescue therapies that can be tried to improve oxygenation in the acute setting (summarized in Table 67-4). Although previously viewed primarily as a rescue therapy, prone positioning improved mortality in moderately severe ARDS in one study¹⁵⁷ and is now being used more frequently in routine care of patients with moderately severe ARDS ($\text{PaO}_2/\text{FiO}_2 < 150$) in addition to its utility in improving oxygenation in the setting of refractory hypoxemia. Extracorporeal membrane oxygenation (ECMO) has been used in patients with ARDS and severe hypoxemia. In specialized centers ECMO has been used successfully to treat patients with severe ARDS.¹⁸⁷⁻¹⁸⁹ One large trial randomizing 180 patients with severe ARDS to ECMO versus conventional management showed improved survival without disability at 6 months in patients treated with ECMO.¹⁹⁰ In this study, patients randomized to ECMO were transferred to a specialty center to receive therapy. Upon arrival, only 75% of patients in the ECMO group were actually treated with ECMO. The study design makes it difficult to determine whether the transfer to a specialty center for care or the ECMO itself conferred benefit. Although the results of this study are encouraging, the need for transfer to a specialty center and the dropout rate of 25% upon transfer limit the generalizability of this study; additional clinical trials are under way. High-frequency oscillatory ventilation (HFOV) appeared to be promising in several small, randomized trials in patients with ARDS,¹⁹¹⁻¹⁹⁵ with improvements in oxygenation in patients with severe hypoxemia. However, two large, randomized clinical trials in severe ARDS failed to show a benefit,^{196,197} and in one of the trials, mortality was higher in the HFOV group.¹⁹⁶ For this reason, HFOV should only be used as a rescue therapy and only by experienced operators. Other rescue therapies include the use of a pulmonary vasodilator, such as inhaled nitric oxide (NO) or inhaled prostacyclin. There have been several small, randomized clinical trials of inhaled NO in ARDS; although none has shown improved mortality, its use has been associated with improvements in oxygenation.¹⁹⁸ Inhaled prostacyclin is another pulmonary vasodilator that may be used as a rescue therapy in severe, refractory ARDS, although there are no randomized trials showing a mortality benefit.¹⁹⁹

COMPLICATIONS

Complications are common in any critically ill patient population. Supportive care for all critically ill patients must include vigilance in both preventing and diagnosing common complications such as pulmonary embolus, acute myocardial infarction, gastrointestinal

TABLE 67-4 Summary of Rescue Therapies for Acute Lung Injury and Acute Respiratory Distress Syndrome

| RESCUE THERAPY | YEAR | HOW STUDIED | NUMBER OF PATIENTS | COMMENTS | REFERENCES |
|---|------|-------------|--------------------|---|------------|
| ECMO | 1979 | Phase III | 90 | In this multicenter trial there was no benefit with the use of ECMO. | 241 |
| | 2009 | Phase III | 180 | This large, randomized trial showed benefit to treatment with ECMO; however, 25% of patients assigned to ECMO did not receive this therapy, and the need for urgent transfer to specialized treatment centers limits general applicability of this trial. | 190 |
| ECCOR | 1994 | Phase III | 40 | This newer form of extracorporeal therapy did not improve mortality. | 204 |
| Prone positioning | 2001 | Phase III | 304 | Although prone positioning improved oxygenation, there was no mortality benefit | 155 |
| | 2009 | Phase III | 342 | Patients were randomized according to severity of hypoxemia to receive 20 hours of prone positioning vs. usual care and had no reduction in mortality at 28 days or 6 months. | 156 |
| | 2013 | Phase III | 466 | Patients with more severe ARDS ($\text{PaO}_2/\text{FiO}_2 < 150$ mm Hg) were randomized to supine or prone position (>16 h/day). Patients in the prone group had improved 28-day mortality. | 157 |
| High-frequency oscillatory ventilation (HFOV) | 2002 | Phase III | 148 | HFOV group had improved oxygenation but no difference in mortality. | 191 |
| | 2005 | Phase III | 61 | No significant differences in any outcome between the groups | 195 |
| | 2013 | Phase III | 548 | HFOV had higher mortality and more hemodynamic instability. | 196 |
| | 2013 | Phase III | 795 | No difference in mortality | 197 |
| Inhaled nitric oxide | 1998 | Phase II | 177 | Although some patients will have improvement in oxygenation with inhaled nitric oxide, there was no mortality benefit in any of these large studies. | 242 |
| | 1999 | Phase III | 203 | | 243 |
| | 2004 | Phase III | 385 | | 244 |

PEEP, positive end expiratory pressure; ECMO, extracorporeal membrane oxygenation; ECCOR, extracorporeal CO₂ removal.

bleeding, and nosocomial infection. Certain complications are more common in ARDS patients and deserve special mention.

Barotrauma

Barotrauma occurs when air dissects out of the airways or alveolar space into surrounding tissues, leading to pneumothorax, pneumomediastinum, pneumatocele, or subcutaneous emphysema (Fig. 67-5). The exact incidence of pulmonary barotrauma in ARDS is unclear but appears to be declining. Data from two large, randomized trials of protective ventilatory strategies suggest an incidence of early pneumothorax of 12% to 13%.^{200,201} Higher incidences have been reported in the past, a finding that may have been the result of using mechanical ventilation with high tidal volumes and very high inspiratory plateau pressures.²⁰² In 861 patients enrolled in the NIH ARDS Network trial, approximately 10% developed some form of barotrauma, regardless of whether they were in the 6- or 12-mL/kg tidal volume arm. Further, PEEP level was the only factor that predicted the development of barotrauma in a multivariate analysis.²⁰³

Treatment of barotrauma depends on the location of the extravasated air. Pneumothorax can be life threatening, particularly if it is under tension; immediate diagnosis and tube thoracostomy are essential. Pneumothorax should be considered in any mechanically ventilated patient with ARDS who develops sudden, unexplained worsening of hypoxemia, respiratory distress, or hemodynamic instability. A chest radiograph (preferably upright) is usually sufficient to make the diagnosis, but in many cases there may not be time to obtain one (see Fig. 67-5). Pneumomediastinum and subcutaneous emphysema can be painful but do not require specific therapy other than analgesia. Air embolus is a potentially fatal complication of positive pressure mechanical ventilation that has been reported occasionally in patients with ARDS²⁰⁴⁻²⁰⁶ and usually occurs in conjunction with other evidence of pulmonary barotrauma, often simultaneously.

Nosocomial Pneumonia

The incidence of nosocomial pneumonia in patients with ARDS is difficult to quantify. Depending on the diagnostic definition and/or strategy employed, estimates range from 15% to 60%.^{207,208} There is no

FIGURE 67-5 ■ Chest radiograph showing tension pneumothorax in a patient with acute respiratory distress syndrome.

consensus regarding the appropriate way to diagnose nosocomial pneumonia in the mechanically ventilated patient. Since patients with ARDS frequently die from uncontrolled infection, recognition (though notably difficult) and treatment of nosocomial pneumonia is an important part of caring for the ARDS patient. Clinical criteria commonly used in the diagnosis of nosocomial pneumonia include fever, elevated WBC count, purulent secretions, and pulmonary infiltrates. However, these signs are often present in patients with ARDS, even in the absence of nosocomial pneumonia.²⁰⁹ Autopsy studies of patients who died with ARDS show a high incidence of unsuspected pneumonia.²¹⁰⁻²¹² An

in-depth discussion of diagnostic strategies is presented elsewhere in this text. Regardless of the methods used for diagnosis, early, appropriate, and empiric therapy is the mainstay of treatment for nosocomial pneumonia. The adequacy and timeliness of initial empiric therapy are important determinants of outcome. Knowledge of local resistance patterns is crucial, and a high index of suspicion is required.

Multiorgan System Dysfunction

Although ARDS is often thought of as a primary pulmonary disorder, ARDS is often a systemic disorder with many similarities to sepsis or SIRS. Multiorgan system dysfunction is a common complication in ARDS. Organ dysfunction may result from the underlying cause of ARDS, such as sepsis, or occur independently. The exact incidence of multiorgan system dysfunction in ARDS is difficult to quantify. In the ARDS Network trial of low tidal volume ventilation, the mean number of nonpulmonary organ system failures per patient was 1.8.²⁰⁰ Given the simultaneous occurrence of multiple organ failures, it is often difficult to determine the exact cause of death in ARDS patients, and survival ultimately depends on successful support of the failing organs.

Neuromuscular Weakness

Patients with ARDS are at high risk for developing prolonged muscle weakness that persists after resolution of pulmonary infiltrates and can complicate weaning from mechanical ventilation and rehabilitation. This clinical syndrome is commonly called *critical illness polyneuropathy* but has components of neuropathy and myopathy that can coexist or occur separately.²¹³ Although little prospective data is available, several studies suggest that neuromuscular abnormalities are persistent in many survivors of critical illness, even when studied up to 5 years after ICU discharge.^{121,214} Prolonged muscle weakness is most common in critically ill patients who are treated with glucocorticoids. In one study, the use of corticosteroids was shown to be the best independent predictor of ICU-acquired paresis (odds ratio, 14.9; 95% CI, 3.2–69.8).²¹⁵ In the absence of a compelling clinical indication such as underlying connective tissue disease, the use of glucocorticoids should not be routine unless new clinical evidence in support of their clinical utility in ARDS becomes available. In other studies, neuromuscular blockade has also been implicated.

CLINICAL OUTCOMES AND PROGNOSIS

Once a patient develops ARDS, several prognostic factors can help clinicians to predict the outcome. An elevated pulmonary dead space fraction in ARDS is a reflection of extensive injury to the lung microcirculation, lung microvascular thrombi, and regional differences in pulmonary blood flow and is a predictor of death in patients with ARDS.^{216,217} Although the dead space fraction may predict mortality, it is not routinely measured in the ICU. For this reason, predictive models that use readily available clinical variables have been developed.²¹⁸ In addition to dead space fraction, a positive cumulative fluid balance at day 4 in patients with ARDS predicts increased mortality,²¹⁹ further supporting the use of a conservative fluid strategy in patients with ARDS.¹³⁴

The reported mortality from ARDS appears to be gradually declining,¹²² although this finding has not been consistent between retrospective studies.²²⁰ Before the 1990s, mortality in clinical trials was approximately 40% to 60%.²²¹ Several recent single-center studies

suggest that mortality rates measured in the same centers has declined over time.^{222–225} In an ARDS Network study that enrolled 861 ARDS patients in the late 1990s, aggregate mortality to hospital discharge was 31% in the 6-mL/kg tidal volume arm and 40% in the 12-mL/kg tidal volume arm. However, mortality data from this study may significantly underestimate overall ARDS mortality since many severely ill patients were excluded, including those with advanced liver disease, bone marrow transplantation, severe chronic respiratory disease, burns greater than 30% body surface area, or any other underlying condition with a likelihood of death greater than 50% within 6 months. As has been observed in other studies, the risk of in-hospital mortality in this study was highest in those with sepsis (43%), intermediate in those with pneumonia (36%) or aspiration (37%), and lowest in those with multiple trauma (11%).¹⁶ The low-tidal volume strategy was effective at reducing mortality across all causes of ARDS.¹⁶ Another study has shown that implementation of the ARDS Network low-tidal volume ventilator strategy is associated with lower hospital mortality compared to historical controls.²²⁶ In a more recent ARDS Network study published in 2012, the overall 60-day mortality was 23%.¹⁴²

Several recent multicenter studies in France,²²⁷ Sweden,²²⁸ Australia,²²⁹ and Argentina²³⁰ attempted to define mortality and prognostic variables in observational, population-based studies rather than from clinical trial participants. In these studies, mortality was variable, ranging from 32% for mild ARDS to 58% to 60% for moderate to severe ARDS. Factors independently associated with mortality from ARDS varied from study to study and included age, Acute Physiology Score, $\text{PaO}_2/\text{FiO}_2$ ratio, organ failures or septic shock, immunosuppression, cardiovascular failure, and chronic liver disease.^{30,227–230} Two other U.S. studies of patients with ARDS predominantly from medical intensive care units reported high overall mortality rates (58%).^{231,232} Mortality was associated with chronic liver disease and other underlying disease such as HIV infection or cancer. Although most studies have reported short-term mortality from ARDS, a recent study examined 1-year mortality.²³³ In a heterogeneous group of 641 patients with ARDS, 1-year mortality was substantially higher than hospital mortality (41% vs. 24%; $P < 0.0001$). In summary, these studies suggest that while some improvements in ARDS mortality have been made, mortality remains quite high in population-based studies, and improvements in short-term outcomes may not be reflected in better long-term outcomes.

ARDS survivors frequently have long-term functional disability, cognitive dysfunction, and psychosocial problems.²³⁴ Interestingly, pulmonary function frequently returns to normal or near-normal in survivors. In a report of 1-year follow-up in 109 survivors of ARDS,¹²⁰ lung volumes and spirometry had returned to normal by 6 months. However, carbon monoxide diffusing capacity was persistently low throughout the year. Six-minute walk distances were persistently low at 12 months, largely due to muscle wasting and weakness rather than pulmonary function abnormalities.¹²⁰ Treatment with any systemic corticosteroid, the presence of illness acquired during the ICU stay, and the rate of resolution of the lung injury and multiorgan dysfunction during the ICU stay were the most important determinants of the 6-minute walk distance during the first year of follow-up. In other studies, patients who survive ARDS are reported to have reduced health-related quality of life²³⁵ and pulmonary-disease-specific health-related quality of life^{236–238} and functional impairment that persists 2 years after ICU discharge.²³⁹ In addition to physical and social difficulties after ARDS, survivors have high rates of depression and anxiety.²⁴⁰

ANNOTATED REFERENCES

Bernard GR, Artigas A, Brigham KL, et al. The American-European Consensus Conference on ARDS: definitions, mechanisms, relevant outcomes, and clinical trial coordination. *Am J Respir Crit Care Med* 1994;149:818-824.

This paper presents the findings of the American-European Consensus Conference on ARDS, including the new definitions for ALI and ARDS that are now widely used both clinically and in research studies.

Herridge MS, Cheung AM, Tansey CM, et al. One-year outcomes in survivors of the acute respiratory distress syndrome. *N Engl J Med* 2003;348:683-693.

In this multicenter study, the authors evaluated 109 survivors of ARDS at 3, 6, and 12 months after discharge from the hospital. Notably, functional disability was very common even at 12 months and was largely caused by muscle wasting and weakness. By contrast, pulmonary function was normalized, with the exception of persistent decrements in the diffusing capacity for carbon monoxide.

Rubenfeld GD. Epidemiology of acute lung injury. *Crit Care Med* 2003;31:S276-S284.

This report is a scholarly review of all the pertinent issues hampering accurate estimate of the incidence of ALI/ARDS.

The Acute Respiratory Distress Syndrome Network. Ventilation with lower tidal volumes as compared with traditional tidal volumes for acute lung injury and the acute respiratory distress syndrome. *N Engl J Med* 2000;342:1301-1308.

This was a multicenter trial of 6-mL/kg compared with 12-mL/kg tidal volume in 861 mechanically ventilated patients with ALI or ARDS. The major finding was a reduction in hospital mortality in the 6-mL/kg group from 40% to 31%.

Ware LB, Matthay MA. Medical progress: the acute respiratory distress syndrome. *N Engl J Med* 2000;342:1334-1349.

This review article presents a comprehensive overview of the pathogenesis, clinical features, and treatment of ALI and ARDS.

Ware LB, Matthay MA. Clinical practice. Acute pulmonary edema. *N Engl J Med* 2005;353:2788-2796.

This case-based review article highlights the pathophysiologic and clinical differences between hydrostatic pulmonary edema and ARDS and provides a clinical algorithm for differentiating between the two.

The National Heart, Lung, and Blood Institute Acute Respiratory Distress Syndrome (ARDS) Clinical Trials Network. Pulmonary-artery versus central venous catheter to guide treatment of acute lung injury. *N Engl J Med* 2006;354:2213-2224.

The National Heart, Lung, and Blood Institute Acute Respiratory Distress Syndrome (ARDS) Clinical Trials Network. Comparison of two fluid-management strategies in acute lung injury. *N Engl J Med* 2006;354:2564-2575.

These companion papers present the main findings from the ARDS Network Fluid and Catheter Treatment Trial (FACTT). The major findings from these two reports are that patients with ARDS who are not in shock should have central-venous-pressure-directed management of a conservative fluid strategy with a goal CVP of <4; such patients had more ventilator-free days compared to patients treated with a liberal fluid strategy.

Rice TW, Wheeler AP, Bernard GR, Hayden DL, Schoenfeld DA, Ware LB. Comparison of the $\text{SpO}_2/\text{FiO}_2$ ratio and the $\text{PaO}_2/\text{FiO}_2$ ratio in patients with acute lung injury or ARDS. *Chest* 2007;132:410-417.

This study compares the use of the $\text{SpO}_2/\text{FiO}_2$ ratio to the more invasive $\text{PaO}_2/\text{FiO}_2$ ratio, which requires blood gas analysis for the diagnosis of ARDS and should improve the rate of ALI/ARDS diagnosis among clinicians. In this study, an S/F ratio of 235 corresponded to a P/F ratio of 200, while an S/F ratio of 315 corresponded to a P/F ratio of 300.

Aspiration is defined as the misdirection of oropharyngeal or gastric contents into the larynx and lower respiratory tract.¹ The pulmonary syndromes that commonly follow aspiration depend on the quantity and nature of the aspirated material, frequency of aspiration, and the nature of the host's defense mechanisms. The most important syndromes include *aspiration pneumonitis*, or Mendelson syndrome, a chemical pneumonitis caused by the aspiration of gastric contents, and *aspiration pneumonia*, an infectious process caused by the aspiration of oropharyngeal secretions colonized by pathogenic bacteria.¹ There is some overlap between these two syndromes, but they are distinct clinical entities. Other aspiration syndromes include airway obstruction, lung abscess, exogenous lipoid pneumonia, chronic interstitial fibrosis, and *Mycobacterium fortuitum* pneumonia.

■ ASPIRATION PNEUMONITIS

Aspiration pneumonitis is best defined as acute lung injury following the aspiration of regurgitated gastric contents.¹ This syndrome usually occurs in patients with a marked disturbance of consciousness, such as drug overdose, seizures, coma due to acute neurologic insults, and massive cerebrovascular accident, following head trauma and during anesthesia. In clinical practice, drug overdose is the most common cause of aspiration pneumonitis, occurring in approximately 10% of patients hospitalized following a drug overdose. Historically the syndrome most commonly associated with aspiration pneumonitis is Mendelson's syndrome, reported in 1946 in obstetric patients who aspirated while receiving general anesthesia.²

Although aspiration is a widely feared complication of general anesthesia, clinically apparent aspiration in modern anesthesia practice is exceptionally rare, and in healthy patients the overall morbidity and mortality are low. Nevertheless, aspiration pneumonia is an important perioperative complication and remains the most common cause of anesthesia-related death. The risk of aspiration with modern anesthesia is reported to be between 2.9 and 4.7 per 10,000 general anesthetics (about 1 in 3000 anesthetics) with a mortality of approximately 1:125,000, accounting for between 10% and 30% of all anesthetic deaths.^{3,4} Emergency surgery (particularly, trauma and abdominal surgery with delayed gastric emptying) procedures performed at night, inadequate anesthesia, obesity, elderly immobilized patients, and patients with obstructive sleep apnea are considered to be at a higher risk of aspiration.^{4,5}

Pathophysiology

Mendelson emphasized the importance of acid when he showed that un-neutralized gastric contents introduced into the lungs of rabbits caused severe pneumonitis indistinguishable from that caused by an equal amount of 0.1 N hydrochloric acid.^{2,6,7} However, if the pH of the vomitus was neutralized before aspiration, the pulmonary injury was minimal. Experimental studies have demonstrated that the severity of lung injury increases significantly with the volume of the aspirate and indirectly with its pH, with a pH of less than 2.5 being required to cause aspiration pneumonitis. However, the stomach contains a variety of other substances in addition to acid that may be damaging when aspirated. Several experimental studies have revealed that aspiration of

small, particulate food matter from the stomach may cause severe pulmonary damage, even if the pH of the aspirate is above 2.5.^{8,9} These studies suggest that cell recruitment and expression of inflammatory mediators are most pronounced after injury with combined acid and small food particles. Such data are supported by findings in patients where the most severe lung injury was observed following aspiration with particulate food matter.^{10,11}

Clinical Presentation

Aspiration of gastric contents can present dramatically with a full-scale occurrence that includes gastric contents in the oropharynx, wheezing, coughing, shortness of breath, cyanosis, pulmonary edema, hypotension, and hypoxemia, which may progress rapidly to severe ARDS and death. However, after the aspiration of gastric contents, many patients may not develop such signs or symptoms, while others may develop a cough or wheeze. In some patients, aspiration may be clinically silent, manifesting only as arterial desaturation with radiologic evidence of aspiration. Warner and colleagues studied 67 patients who aspirated while undergoing anesthesia.⁷ Forty-two (64%) of these patients were completely asymptomatic, 13 required mechanical ventilatory support for more than 6 hours, and four died.

Management of Aspiration Pneumonitis

The upper airway should be suctioned following a witnessed aspiration. Endotracheal intubation should be considered in patients who are unable to protect their airway. While a common practice, the prophylactic use of antibiotics in patients with suspected or witnessed aspiration is not recommended. Similarly, the use of antibiotics shortly after an aspiration episode in a patient who develops a fever, leukocytosis, and a pulmonary infiltrate is discouraged as it may select for more resistant organisms in a patient with an uncomplicated chemical pneumonitis. However, empiric antimicrobial therapy is appropriate in patients who aspirate gastric contents in the setting of small bowel obstruction or other circumstances associated with the colonization of gastric contents. Antimicrobial therapy should be considered in patients with aspiration pneumonitis that fails to resolve within 48 hours. When antimicrobial agents are used, broad-spectrum coverage is recommended. Antimicrobials with anaerobic activity are not routinely required.

Corticosteroids have been used in the management of aspiration pneumonitis since 1955.¹² However, due to a limited amount of outcome data, it is not possible to make evidence-based recommendations on the use of these agents in patients with aspiration pneumonia.

■ ASPIRATION PNEUMONIA

Aspiration pneumonia refers to the development of a radiographic infiltrate in the setting of patients with risk factors for increased oropharyngeal aspiration. Approximately half of all healthy adults aspirate small amounts of oropharyngeal secretions during sleep. Presumably, the low virulent bacterial burden of normal pharyngeal secretions together with forceful coughing, active ciliary transport, and normal

humoral and cellular immune mechanisms result in clearance of the inoculum without sequelae. However, if mechanical, humoral, or cellular mechanisms are impaired or if the aspirated inoculum is large enough, pneumonia may follow. Any condition that increases the volume and bacterial burden of oropharyngeal secretions in the setting of impaired host defense mechanisms may lead to aspiration pneumonia. Indeed, in stroke patients undergoing a swallow evaluation, there is a strong correlation between the volume of the aspirate and the development of pneumonia.¹³ Factors that increase oropharyngeal colonization with potentially pathogenic organisms and increase the bacterial load may augment the risk of aspiration pneumonia.

The clinical setting in which pneumonia develops largely distinguishes aspiration pneumonia from other forms of pneumonia. However, there is a great deal of overlap. This is illustrated by the fact that otherwise healthy elderly patients with “community-acquired pneumonia” have been demonstrated to have a significantly higher incidence of silent aspiration when compared with age-matched controls.¹⁴

Epidemiology

The lack of specific and sensitive markers of aspiration makes the epidemiologic study of aspiration syndromes difficult. Furthermore, most studies do not make the distinction between aspiration pneumonitis and aspiration pneumonia. Nevertheless, several studies list “aspiration pneumonia” as the cause of community-acquired pneumonia (CAP) in 5% to 15% of cases.^{15,16} CAP is a major cause of morbidity and mortality in the elderly, and it is likely that aspiration is the major cause of pneumonia in these patients. Epidemiologic studies have demonstrated that the incidence of pneumonia increases with aging, with the risk being almost six times higher in those over the age of 75, compared to those less than 60 years of age.^{17,18} The attack rate for pneumonia is highest among those in nursing homes.¹⁹

Dysphagia in Patients with Aspiration Pneumonia

Dysphagia is a major risk factor leading to aspiration pneumonia. In addition, dysphagia contributes significantly to protein-energy malnutrition and dehydration. Impairment in any component of the swallow mechanism, including anatomic abnormalities of the upper airway or esophagus, can lead to dysphagia. Dysphagia has traditionally been associated with brainstem and bilateral cerebral infarction though it has more recently been shown also to occur in isolated cerebral infarctions. Furthermore, dysphagia is commonly associated with silent cerebral infarction.

Dysphagia is common in Westernized nations and is a major cause of morbidity and mortality. Indeed, aspiration pneumonia is likely the final common pathway by which many chronically ill patients die. It has been estimated that over 16 million senior citizens in the United States suffer from dysphagia.²⁰ Furthermore, an additional 300,000 to 600,000 patients develop dysphagia each year in the United States from neurologic disorders.²¹ Dysphagia affects more than 30% of patients who have had a cerebrovascular accident, 52% to 82% of patients with Parkinson's disease, 84% of patients with Alzheimer's disease, up to 40% of adults aged 65 years and older, and more than 60% of institutionalized elderly patients.²²

The efficiency of the swallow mechanism decreases with aging, thereby increasing the risk of aspiration and pneumonia in the elderly. Kikuchi and colleagues evaluated the occurrence of silent aspiration in otherwise “healthy elderly patients” with CAP and age-matched control subjects using indium chloride scanning.¹⁴ Silent aspiration was demonstrated in 71% of patients with CAP compared to 10% in control subjects. The impaired swallow mechanism in the elderly can be attributed to diminished sensation, silent cerebral infarction, cerebral atrophy, a delay in the synapse conduction in the afferent inputs to the central nervous system, and lingual weakness (sarcopenia) caused by aging.^{23,24}

TABLE 68-1

Risk Factors for Dysphagia and Aspiration Pneumonia

| • Presbyesophagus |
| • Achalasia |

Risk Factors for Dysphagia

The major risk factors for dysphagia are listed in Table 68-1. In patients with an acute stroke, the incidence of dysphagia ranges from 40% to 70%.²⁵ Dysphagic patients who aspirate are at an increased risk of developing pneumonia.^{26,27} Although dysphagia improves in most patients following a stroke, in many the swallowing difficulties follow a fluctuating course with 10% to 30% continuing to have dysphagia with aspiration.^{28,29}

Factors That Increase the Risk of Pneumonia in Patients Who Aspirate

While the presence of dysphagia and the volume of the aspirate are key factors that predispose patients to aspiration pneumonia, a number of other factors also play an important role.¹³ Colonization of the oropharynx is an important step in the pathogenesis of aspiration pneumonia. The elderly have increased oropharyngeal colonization with pathogens, such as *Staphylococcus aureus* and aerobic gram-negative bacilli (e.g., *Klebsiella pneumoniae* and *Escherichia coli*). Although such increased colonization may be transient, it underlies the increased risk in the elderly of pneumonia due to these pathogens. Furthermore, colonization of dental plaque may be an important risk factor for aspiration pneumonia.³⁰ The defects in host defenses that predispose some individuals to enhanced colonization with these organisms are uncertain. However, dysphagia with a decrease in salivary clearance and poor oral hygiene may be major risk factors.³¹ Residents of long-term care facilities are prone to poor oral health due to lack of oral hygiene care, as well as conditions of periodontal and/or dental disease. In addition, proton pump inhibitors (PPIs) increase gastric and oropharyngeal colonization with potentially pathogenic organisms. Gulmez and colleagues reported that the concurrent use of PPI in patients over the age of 60 years increased the risk for community-acquired (aspiration) pneumonia.³²

Diagnosis and Management of Aspiration Pneumonia

There is no “gold standard” test to diagnose aspiration. Furthermore, unlike the case of aspiration pneumonitis, in patients with aspiration pneumonia the aspiration episode is not witnessed. The diagnosis is therefore inferred when a patient with known risk factors for aspiration has an infiltrate in a characteristic bronchopulmonary segment. In patients who aspirate in the recumbent position, the most common sites of involvement are the posterior segments of the upper lobes and

the apical segments of the lower lobes. In patients who aspirate in the upright or semirecumbent position, the basal segments of the lower lobes are favored. The typical picture is that of an acute pneumonic process, which runs a course similar to that of a typical CAP. Untreated, however, these patients also appear to have a higher incidence of cavitation and lung abscess formation.³³

Antimicrobial therapy is indicated in patients with aspiration pneumonia. The choice of antibiotics should depend on the setting in which the aspiration occurs, as well as the patient's premorbid condition. This includes such factors as whether the aspiration occurred in the community or a health care facility and patient characteristics such as alcoholism, oral hygiene, intravenous drug abuse, and the recent use of antibiotics or acid suppressive therapy.³⁴

Aspiration pneumonia most commonly occurs in the setting of a health care facility (HCAP) or an acute care hospital (HAP). Health care-associated aspiration pneumonia (HCAP) refers to pneumonia that develops in individuals receiving health care outside the hospital setting, including dialysis, nursing homes, and long-term acute care (LTAC) facilities. Patients with HCAP who have risk factors for infection with a drug-resistant pathogen should be treated with broad-spectrum agents.

Although commonly prescribed (and often considered the standard of care) antimicrobials with specific anaerobic activity are not routinely warranted. In the most rigorous study to date, El-Sohl and colleagues performed protected quantitative bronchial sampling in 95 patients with severe aspiration pneumonia.³⁵ Out of the 67 pathogens identified, gram-negative enteric bacteria were the predominant organisms isolated (49%), followed by anaerobic bacteria (16%), and *Staphylococcus aureus* (12%). A single anaerobic bacterium was isolated from 11 patients, usually in association with a gram-negative pathogen. Although seven cases with anaerobic isolates received initially inadequate antimicrobial therapy, six had an effective clinical response. Antimicrobials with specific anaerobic activity may only be indicated in patients with periodontal disease, patients expectorating putrid sputum, and patients with necrotizing pneumonia or lung abscess on a chest radiograph.^{1,34,36,37}

Assessment and Management of Dysphagia

All elderly patients with CAP and chronic idiopathic lung disease, as well as patients with a recent cerebrovascular accident and those with degenerative neurologic diseases, should be referred to a speech and language pathologist for a formal swallow evaluation.^{27,38} Patients with dysphagia require the formulation and implementation of an individualized management strategy. A clinician's bedside assessment of a cough and gag reflex is unreliable in screening for patients at risk of aspiration. Because objective swallowing evaluation can be performed with an nasogastric (NG) tube (or feeding tube) in place, it is not necessary to remove the NG tube (and interrupt enteral feedings) to evaluate dysphagia. Similarly, there is no contraindication to leaving an NG tube in place to supplement oral alimentation.³⁹

The management of patients with dysphagia requires the coordinated expertise of a number of health care professionals, including the patients' primary care physician, pulmonologist, speech and language pathologist, clinical dietician, occupational therapist, physiotherapist, nurse, oral hygienist, and dentist, as well as the patients' primary caregivers. The goal is to optimize the safety, efficiency, and effectiveness of the oropharyngeal swallow, to maintain adequate nutrition and hydration and improve oral hygiene. Enhanced quality of life, wherever possible, should direct management. Approaches to management should emphasize oral versus nonoral nutritional intake and hydration.

A fundamental principle of rehabilitation is that the best therapy for any activity is the activity itself; as swallowing may be considered the best therapy for swallowing disorders, rehabilitation should be aimed at identifying ways of ensuring safe and effective swallowing in individual patients. Current treatment for dysphagia includes the prevention of aspiration in the form of diet and fluid modifications,

compensatory maneuvers, position changes, and rehabilitation exercises.⁴⁰ Diet modification is also a common treatment for dysphagia. Modifications in food consistency are individually determined by means of the clinical swallow and videofluoroscopic swallow evaluation. A reduction in bolus volume and enhancement of bolus viscosity significantly improve the safety of swallowing and reduce the risk of aspiration.²³ In addition to changes in diet, maintenance of oral feeding often requires compensatory techniques to reduce aspiration or to improve pharyngeal clearance. A variety of behavioral techniques are used, including modifications in posture, head position, and respiration, as well as specific swallowing maneuvers.

Tube Feeding

Tube feeding is not essential in all patients who aspirate. However, short-term tube feeding, may be indicated in elderly patients with severe dysphagia and aspiration in whom improvement of swallowing is likely to occur. Nakajoh and colleagues demonstrated that the incidence of pneumonia was significantly higher in stroke patients with dysphagia who were fed orally compared to those who received tube feeding (54.3% vs. 13.2%, $P < 0.001$), despite the fact that the orally fed patients had a higher functional status (higher Barthel index).⁴¹ The FOOD trials consisted of two large randomized studies that enrolled dysphagic stroke patients.⁴² In the first trial, patients enrolled within 7 days of admission and were randomly allocated to early tube feeding or no tube feeding. Early tube feeding was associated with an absolute reduction in the risk of death to 5.8%. The second trial allocated patients to early NG feeding or early feeding via a percutaneous endoscopic gastrostomy (PEG) tube. PEG feeding was associated with an absolute increase in the risk of death to 1% and an increased risk of death or poor outcome of 7.8%. Patients with a PEG were less likely to be transitioned to oral feeding than the NG group and were more likely to be living in an institution. This difference in patient location may in part explain the higher mortality rate of the PEG-fed patients. Furthermore, PEG-fed patients were more likely to develop pressure sores, suggesting that these patients may have been nursed differently. The results of the FOOD trials suggest that dysphagic stroke patients should be fed early via a NG or feeding tube and transitioned to oral feeding as their dysphagia resolves. Those patients whose dysphagia does not resolve may be candidates for placement of a PEG tube.

Oral Hygiene

Dental plaque as well as "tongue coating" serves as a reservoir of potentially pathogenic organisms.³⁰ Occupants of residential homes have been shown to have poor oral hygiene and rarely receive treatment from dentists and oral hygienists.⁴³ An aggressive protocol of oral care will reduce colonization with potentially pathogenic organisms and decrease the bacterial load, measures which have been demonstrated to reduce the risk of aspiration pneumonia.⁴⁴⁻⁴⁷ Oral care should not be overlooked in edentulous patients, as "tongue cleaning" is associated with a decreased oropharyngeal bacterial load.^{48,49}

Pharmacologic Management

The neurotransmitter, Substance P, is believed to play a major role in both a cough and swallow sensory pathways. Angiotensin-converting enzyme (ACE) inhibitors prevent the breakdown of Substance P and may theoretically be useful in the management of patients with aspiration pneumonia. A number of studies have demonstrated a lower risk of aspiration pneumonia in stroke patients treated with an ACE inhibitor compared with other antihypertensive agents.^{50,51} This observation was initially noted in Japanese patients, and it has been suggested that this benefit was restricted to Asian populations.⁵² Furthermore, it has been postulated that lipophilic ACE inhibitors may be more beneficial than hydrophilic ACE inhibitors.⁵³ However, a population-based case-control study from the UK demonstrated that current prescription for an ACE inhibitor was associated with a reduction in the risk of pneumonia in the general population (odds ratio: 0.75; 95% confidence interval: 0.65 to 0.86).⁵⁴

CONCLUSIONS

Aspiration pneumonia and pneumonitis are common clinical syndromes. Aspiration pneumonitis follows the aspiration of gastric contents, usually in patients with a marked decreased level of consciousness. Treatment of aspiration pneumonitis is essentially

supportive. Aspiration pneumonia occurs in patients with dysphagia and usually presents as CAP or health care associated pneumonia with a focal infiltrate in a dependent bronchopulmonary segment. Patients with aspiration pneumonia require treatment with antibiotics selected on the basis of the risk of infection with a drug-resistant pathogen and management of the underlying dysphagia.

MAGNITUDE OF THE PROBLEM

Each year in the United States, acute asthma accounts for approximately 1.9 million emergency department (ED) visits, 480,000 hospitalizations, and 3400 deaths.¹ While failure to achieve outpatient control underlies many of these poor outcomes, a minority of patients present to the ED on oral corticosteroids or after a recent oral steroid taper.^{2,3} Factors underlying the exacerbation-prone phenotype include cigarette smoking, medication nonadherence, psychosocial factors, poverty, obesity, and alterations in host cytokine response to viral infections.⁴ The rate of asthma death is higher in blacks than whites and in patients aged 65 and older. Patients who require mechanical ventilation for asthma are at low risk for asthma death and pneumothorax, and the rate of asthma death in general has decreased each year since 2000.³ Risk factors for fatal or near-fatal asthma are listed in Table 69-1.

PATHOPHYSIOLOGY OF ACUTE AIRFLOW OBSTRUCTION

Fewer than 15% of asthmatics have rapid-onset exacerbations, which are predominantly bronchospastic events evolving over minutes to hours. They occur from exposure to allergens or irritants, stress, illicit drugs, or the use of nonsteroidal antiinflammatory agents or beta-blockers in susceptible patients. The trigger is generally not infectious.⁵ Asthma attacks more commonly evolve over 24 hours and are associated with increasing airway wall inflammation, bronchospasm, and mucous plugs. These exacerbations are commonly triggered by viral infections or mycoplasma and take longer to resolve.

Regardless of the tempo, critical airflow obstruction follows, and the time available for expiration is insufficient for full exhalation, resulting in gas trapping and dynamic lung hyperinflation (DHI). Trapped gas elevates the alveolar volume and pressure relative to mouth pressure at end expiration, a state referred to as *auto-PEEP*.⁶ Auto-PEEP must be overcome by forcefully lowering pleural pressure during inspiration, increasing inspiratory work. At the same time, DHI increases elastic work, and airway narrowing increases resistive work. Dynamic hyperinflation also places the diaphragm in a disadvantageous position, lowering force generation. In the end, an imbalance between increased work of breathing and decreased respiratory muscle strength can result in respiratory failure.⁷

Hypoxemia results from decreased ventilation (\dot{V}) to perfused (\dot{Q}) alveolar-capillary units. The severity of hypoxemia roughly tracks the severity of obstruction, but in recovering patients, airflow rates may improve faster than PaO_2 , and \dot{V}/\dot{Q} inequality, indicating that larger airways recover faster than smaller airways. Acutely ill asthmatics may also have small areas of high \dot{V} relative to \dot{Q} and increased physiologic dead space, perhaps from decreased blood flow to hyperinflated units. Elevated dead space and decreased alveolar ventilation in the fatiguing patient predisposes to hypercapnia.

Large swings in intrathoracic pressure accentuate the normal inspiratory fall in systolic blood pressure, a phenomenon called *pulsus paradoxus*. During vigorous inspiration, intrathoracic pressure falls, lowering right atrial and right ventricular (RV) pressures and augmenting RV filling. Enhanced right-sided filling shifts the intraventricular septum leftward, causing a conformational change in the left

ventricle (LV), LV noncompliance, and incomplete LV filling. Furthermore, DHI may impede LV filling by causing tamponade-like physiology. LV emptying is affected by large negative pleural pressures and increased LV afterload.

During forced expiration, high intrathoracic pressures impede right-sided filling. The net result of these cyclical changes in pleural pressure is *pulsus paradoxus*. Importantly, a dropping *pulsus paradoxus* does not always signal improvement, as fatigue limits the magnitude of pleural pressure swings.

CLINICAL FEATURES

Patients with moderate to moderately severe attacks are tachypneic and in respiratory distress. They have expiratory phase prolongation and difficulty speaking in long sentences. Arterial blood gases commonly reveal hypoxemia and respiratory alkalosis. Severe attacks lead to upright positioning, diaphoresis, monosyllabic speech, respiratory rate (RR) above 30/min, accessory muscle use, pulse above 120/min, *pulsus paradoxus* greater than 25 mm Hg, hypoxemia, and normo- or hypercapnia. Depressed mental status, paradoxical respiration, bradycardia, absence of *pulsus paradoxus* from fatigue, and a quiet chest signal an impending arrest. The emergence of wheezes in severe patients is generally a good sign that airflow has improved. Posture, speech, and mental status allow for quick appraisal of severity, response to therapy, and need for intubation.⁸ Sinus tachycardia is common, but other cardiac complications occur, including supraventricular and ventricular arrhythmias, right heart strain, and myocardial ischemia. "All that wheezes is not asthma" is an adage worth remembering, and Table 69-2 lists other diagnostic considerations.

PEAK FLOW MEASUREMENTS

Early measurement of the peak expiratory flow rate (PEFR) or forced expiratory volume in the first second of expiration (FEV_1) helps characterize the severity of an attack. As a general rule, a severe attack is characterized by a PEFR less than 200 L/min or an FEV_1 less than 1 L. Objective measures also point to alternate diagnoses when symptoms are not associated with the expected drop in lung function. Objective measurements should be deferred in patients with severe exacerbations because the maneuver can worsen bronchospasm even to the point of arrest.

The change in PEFR or FEV_1 predicts need for hospitalization. Several studies have demonstrated that failure of initial therapy to improve expiratory flow significantly after 30 to 60 minutes predicts a refractory course requiring continued treatment in the ED or hospital.

ACID-BASE STATUS

Arterial blood gases are recommended in patients with severe attacks, but serial gases are generally not necessary unless the patient is mechanically ventilated. Hypoxemia and respiratory alkalosis are common in mild to moderate exacerbations. Eucapnia and hypercapnia indicate a severe exacerbation but are in and of themselves not sufficient reasons for intubation because patients may still respond to pharmacotherapy.

TABLE 69-1 Risk Factors for Fatal or Near-Fatal Asthma

Frequent emergency department visits and hospitalizations
 Intensive care unit admission
 Intubation (prior or current)
 Hypercapnia
 Barotrauma
 Psychiatric illness
 Medical noncompliance
 Illicit drug use
 Poverty
 Inadequate access to medical care
 Use of >two canisters/month of an inhaled β_2 -agonist
 Poor perception of airflow obstruction
 Comorbidities (e.g., coronary artery disease)
 Sensitivity to *Alternaria* species

TABLE 69-2 Differential Diagnosis of Acute Asthma

Chronic obstructive pulmonary disease exacerbation
 Vocal cord dysfunction
 Intraluminal mass or foreign body
 Aspiration
 Tracheal stenosis
 Infectious bronchitis or pneumonia
 Heart failure ("cardiac asthma")

Renal compensation in response to acute respiratory alkalosis of sufficient duration manifests as a normal anion gap metabolic acidosis. Lactic acidosis occurs in patients with labored breathing, particularly in the setting of parenteral β -agonists.

CHEST RADIOGRAPHY

In classic cases of acute asthma, the chest x-ray rarely affects management. Indications for chest imaging include localizing signs on examination, concerns regarding barotrauma, and questions regarding the diagnosis and assessment of endotracheal tube position.

EMERGENCY DEPARTMENT DISPOSITION

Asthmatics with inadequate response to albuterol in the ED invariably require hospital admission or prolonged treatment in the ED.⁹ Approximately one-third of patients are nonresponders to albuterol (Fig. 69-1). These patients have negligible changes in PEFR after 30 to 60 minutes of therapy. Other markers of a severe attack such as a PEFR less than 40% of predicted or personal best, or deterioration despite treatment are indications for admission. Intensive care unit (ICU) admission is required for respiratory failure, the need for frequent albuterol treatments, fatigue, altered mental status, and cardiac toxicity. Patients with an incomplete response to treatment in the ED, defined by improved but persistent symptoms and a PEFR or FEV₁ between 40% and 69% of predicted, should be considered for admission, although select patients may return home safely with appropriate treatment and follow-up. Patients with a good response can be discharged with inhaled antiinflammatory therapy and instructions for follow up.

OXYGEN

Supplemental oxygen is provided to maintain the oxygen saturation above 90%. This improves oxygen delivery to tissues, including the respiratory muscles, and reverses hypoxic pulmonary vasoconstriction. Oxygen further protects against β -agonist-induced pulmonary vasodilation and increased blood flow to low \dot{V}/\dot{Q} units.

FIGURE 69-1 ■ Dose-response relationship to albuterol 4 puffs (400 μ g) every 10 minutes in 116 acute asthmatics, of whom 67% percent obtained discharge criteria after administration of 2.4 mg albuterol within 1 hour; half of the responders met discharge criteria after 12 puffs. Patients with a blunted cumulative dose-response relationship were hospitalized. (Reproduced with permission from Rodrigo C, Rodrigo G. Therapeutic response patterns to high and cumulative doses of salbutamol in acute severe asthma. *Chest* 1998;113:593.)

PHARMACOLOGIC MANAGEMENT

Selected drugs used in the treatment of acute asthma are listed in Table 69-3.

β_2 -Agonists

The bronchospastic component of acute asthma is treated with inhaled, short-acting β_2 -agonists (SABAs). They are delivered in a repetitive or continuous fashion depending on clinical response and side effects, which include tremor, tachycardia, and hypokalemia. A commonly recommended strategy is albuterol, 2.5 mg by nebulization, every 20 minutes during the first hour. In severe asthma exacerbations, continuous administration (same total dose) may be slightly superior to repetitive dosing, although there is little difference between the two strategies in most cases. Albuterol can be delivered effectively by metered dose inhaler (MDI); 4 to 8 puffs of albuterol by MDI with a spacer is equivalent to a 2.5-mg nebulizer treatment. MDIs with spacers are cheaper and faster; handheld nebulizers require less supervision and coordination. Treatment frequency after the first hour depends on the clinical response and side effects.

Although albuterol is the most widely used SABA, other SABAs are available, including levalbuterol. A recent meta-analysis demonstrated that levalbuterol was not superior to albuterol in acute asthma.¹⁰

There is no initial advantage to subcutaneous epinephrine or terbutaline in patients able to comply with inhaled therapy. In refractory

TABLE 69-3

Selected Drugs Used in the Treatment of Acute Asthma

| | |
|-------------------|---|
| Albuterol | 2.5 mg in 2.5 mL normal saline by nebulization every 15-20 min \times 3 in the first hour or 4-8 puffs by MDI with spacer every 10-20 min for 1 hour, then as required; for intubated patients, titrate to physiologic effect and side effects. |
| Levalbuterol | 1.25 mg by nebulization every 15-20 min \times 3 in the first hour, then as required |
| Epinephrine | 0.3 mL of a 1:1000 solution subcutaneously every 20 min \times 3. Terbutaline is favored in pregnancy when parenteral therapy is indicated. Use with caution in patients older than age 40 and in patients with coronary artery disease. |
| Corticosteroids | Methylprednisolone IV or prednisone PO 40-80 mg/d in 1 or 2 divided doses until PEFR reaches 70% of predicted or personal best |
| Anticholinergics | Ipratropium bromide 0.5 mg (with albuterol) by nebulization every 20 min, or 8 puffs by MDI with spacer (with albuterol) every 20 min |
| Magnesium sulfate | 2 g IV over 20 minutes, repeat once as required (total dose 4 g, unless hypomagnesemic) |

IV, intravenous; MDI, metered-dose inhaler; PEFR, peak expiratory flow rate; PO, per os (oral).

cases, however, subcutaneous treatment may be beneficial. Subcutaneous therapy is riskier and should be used with caution in older patients at risk for coronary artery disease. Long-acting β_2 -agonists (LABAs) are not commonly used in acute asthma, although formoterol (which has acute onset of action) is effective and safe in this setting.¹¹ LABA and inhaled corticosteroid (ICS) combination therapy can be initiated or continued in hospitalized patients receiving rescue therapy and may be required to achieve adequate outpatient control.

Ipratropium Bromide

The modest bronchodilator properties of ipratropium bromide preclude its use as a single agent in acute asthma, and the addition of ipratropium to albuterol is of limited benefit in patients with mild or moderate attacks. However, in patients with severe attacks, ipratropium added to albuterol is more effective than albuterol alone.¹² For nebulization in adults, 0.5 mg of ipratropium bromide is added to 2.5 mg of albuterol; by MDI, 4 to 8 puffs of ipratropium bromide are added to 4 to 8 puffs of albuterol. If a combination albuterol/ipratropium bromide inhaler is used, the recommended dose is 4 to 8 puffs every 20 minutes. The combined use of albuterol and ipratropium is indicated for the first 1 to 3 hours as guided by clinical response and toxicity, after which albuterol can be used as a single agent.

Corticosteroids

Systemic corticosteroids are recommended for all patients with acute severe asthma save the rare patient with an immediate and durable response to initial SABA therapy. Corticosteroids treat inflammation by promoting new protein synthesis, and their effects are typically delayed, underlining the importance of early initiation. Systemic steroids decrease hospitalization rates, speed the rate of recovery, and decrease the chance of relapse after discharge.

Oral steroids are as effective as parenteral steroids. Single-dose formulations of an intramuscular preparation are a reasonable choice in patients deemed unlikely to be compliant with oral steroids after discharge.

Various dosing regimens have been studied, and debate continues regarding the optimal dosing strategy. For hospitalized adults, the Expert Panel Report 3 recommends 40 to 80 mg/d of prednisone, methylprednisolone, or prednisolone in 1 or 2 divided doses until PEFR reaches 70% of predicted or the patient's personal best. For

outpatients, a common strategy is to use prednisone, 40 mg/d for 5 to 10 days, with early follow-up to judge clinical response and optimize the outpatient regimen.

There is no established role for high-dose ICSs in acute asthma. However, ICSs play a pivotal role in achieving outpatient asthma control, and patients discharged from the ED or hospital should be started on an ICS-based treatment program.

Other Therapies

Aminophylline does not confer additional bronchodilation in adults compared to standard care with β_2 -agonists. It increases the frequency of adverse effects such as tachyarrhythmias and should only be used in refractory cases.

The safety and efficacy of IV MgSO_4 in adults treated for acute asthma in the ED was the subject of a recent meta-analysis.¹³ The results demonstrate that a single infusion of 1.2 g or 2 g IV MgSO_4 over 15 to 30 minutes reduces hospital admissions and improves lung function in adults with acute asthma who have not responded adequately to supplemental oxygen, SABAs, and IV corticosteroids. There is no established role for inhaled MgSO_4 in acute asthma.¹⁴

There are insufficient data to recommend leukotriene modifiers in acute asthma. The most compelling data come from randomized trials of IV montelukast in adults, but the IV formulation is not available in the United States. There is no benefit to adding oral montelukast to conventional therapy.¹⁵

Methodologic differences, small patient numbers, and failure to control for upper airway obstruction have plagued studies of heliox. Taken in sum, the data do not support its routine use in acute asthma. However, heliox may be reasonable in more severe cases. In addition, data suggest that heliox as a driving gas for nebulized SABAs improves PEFRs and decreases hospital admissions in patients with severe attacks.¹⁶

NONINVASIVE VENTILATION

Despite the common and increasing use of noninvasive ventilation (NIV) in patients with acute asthma, limited data are available to inform its use in this setting. In one small, randomized trial, the addition of NIV to standard therapy accelerated improvement in lung function, decreased the inhaled bronchodilator requirements, and shortened the ICU and hospital lengths of stay.¹⁷ NIV decreases the work of breathing and may allow for more effective delivery of bronchodilators.

Noninvasive ventilation includes the use of low levels of nasal continuous positive airway pressure (CPAP) of 5 to 7.5 cm H_2O or, more commonly, bilevel positive airway pressure (BiPAP). One approach to BiPAP use is to start with 8 cm H_2O inspiratory pressure support and 3 cm H_2O of expiratory positive airway pressure. Pressures are adjusted as required to achieve common endpoints of respiratory rate (RR) below 25/min and tidal volume above 7 mL/kg.¹⁸ Noninvasive ventilation should be used only in alert, cooperative, and hemodynamically stable patients.

INTUBATION AND MECHANICAL VENTILATION

Respiratory arrest or impending arrest (e.g., extreme exhaustion, a quiet chest, progressive hypercapnia, and altered mental status) are indications for intubation. A common problem in the immediate postintubation period is hypotension, which stems from sedation and paralysis, hypovolemia, overzealous mechanical ventilation and possible tension pneumothorax.

Inappropriately fast respiratory rate during mechanical ventilation results in inadequate exhalation time and dangerous levels of dynamic hyperinflation. Clues to this condition include excessive efforts required to deliver manual breathes during Ambu bag ventilation, high airway pressures, hypotension, and tachycardia. When critical-dynamic

hyperinflation is suspected, a trial of hypopnea (2-3 breaths/min) or apnea in a well-oxygenated patient for 30 to 60 seconds is both diagnostic and therapeutic. This maneuver lowers lung volumes and airway pressures and increases cardiac preload to help regain cardiopulmonary stability. Close inspection of the chest radiograph is mandatory to rule out unilateral or bilateral pneumothorax.

Initial Ventilator Settings

Expiratory time (T_e), tidal volume (V_t), and the severity of airway obstruction determine the level of dynamic hyperinflation during mechanical ventilation.^{19,20} Expiratory time is determined by minute ventilation and the inspiratory flow rate. Lowering the respiratory rate prolongs T_e and allows for more complete exhalation (Fig. 69-2). The additional volume of gas emptied by this strategy may be small because of low expiratory flow rates, but even small changes in lung volume may be clinically relevant. Increasing the inspiratory flow rate may also prolong T_e . However, high inspiratory flow rates increase peak airway pressures and may worsen patient-machine synchrony. Furthermore, high inspiratory flow rates may increase the respiratory rate in spontaneously breathing patients and thereby actually decrease T_e . On the other hand, if the inspiratory flow is too low, T_e falls and lung volumes increase.

A reasonable choice for initial settings is an inspiratory flow rate of 60 LPM and an initial minute ventilation of 7 to 8 L/min in a 70-kg patient to avoid dangerous levels of dynamic hyperinflation.²¹ This goal can be achieved by choosing volume-controlled ventilation (VCV) with an RR between 12 and 14/min and a V_t between 7 and 8 mL/kg. In spontaneously breathing patients, a low level of set PEEP (e.g., 5 cm H_2O) decreases the inspiratory work of breathing by decreasing the pressure gradient required to overcome auto-PEEP, without aggravating lung inflation. Theoretically, pressure-controlled ventilation (PCV) may deliver more uniform distribution of ventilation than VCV, but the delivered V_t is more unstable with PCV and is affected by changes in the degree of bronchoconstriction.²² No data support AC

over SIMV with pressure support (PS) for major clinical outcomes in a broad range of patients,²³ but AC is more commonly used.³

Assessing Lung Inflation

The degree of dynamic hyperinflation is central to ventilator adjustments, but measuring lung volumes is challenging in clinical practice. The only validated method is to measure the volume gas at end inspiration, termed V_{ei} , by collecting expired gas from total lung capacity (TLC) to functional residual capacity (FRC) during 40 to 60 seconds of apnea. Although V_{ei} may underestimate air trapping in the presence of slowly emptying lung units, a V_{ei} greater than 20 mL/kg correlates with barotrauma.²¹ The utility of this measure is limited by the need for paralysis and expertise with expiratory gas collection. Alternate measures of lung inflation include the single-breath plateau pressure (Pplat) and auto-PEEP. Accurate measurements of Pplat and auto-PEEP require patient-ventilator synchrony and the absence of patient interference. Paralysis is generally not required. However, neither pressure has been validated as a predictor of outcome. Pplat (or lung distention pressure) is an estimate of average end-inspiratory alveolar pressure that is determined by briefly stopping flow at end inspiration (Fig. 69-3), but Pplat is also affected by properties of the chest wall and abdomen. Pplat is commonly limited to ≤ 30 cm H_2O .

Auto-PEEP is the lowest average alveolar pressure achieved during the respiratory cycle. It is obtained by measuring airway opening pressure during an end-expiratory hold maneuver (see Fig. 69-3). The persistence of expiratory gas flow at the beginning of inspiration (which can be detected by auscultation or flow tracings) also suggests auto-PEEP (see Fig. 69-2). Auto-PEEP may be underestimated when there is poor communication between alveoli and the airway opening.

Ventilator Adjustments

Although adjusting ventilator settings according to Pplat has not been validated in controlled trials, we recommend limiting Pplat as a general principle of management and suggest the following approach (Fig. 69-4). If initial ventilator settings result in Pplat above 30 cm H_2O , we lower the respiratory rate to decrease Pplat below 30 cm H_2O . While this maneuver may result in hypercapnia, this is generally well

FIGURE 69-2 ■ Effects of changing respiratory rate (RR) on expiratory time (T_e) with a V_t of 1000 mL and a constant inspiratory flow rate of 60 LPM (1 LPS). Note that with RR of 15/min, total cycle time (amount of time allowed for one complete breath) is 4 seconds. Inspiratory time (T_i) is 1 second, and T_e is 3 seconds, resulting in an I:E of 1:3. Note that the expiratory flow persists at the time of the next delivered breath (as demonstrated by failure of the exhalation flow tracing to return to baseline or zero flow), suggesting the presence of auto-PEEP. By lowering RR to 10/min total cycle time increases to 6 seconds, and T_e is 5 seconds, resulting in an I:E of 1:5. Lower RR allows for greater exhalation of the delivered breath and lower end-expiratory plateau pressure (not shown), although effects are modest because of low end-expiratory flow rates.

FIGURE 69-3 ■ Pressure-time tracing during mechanical ventilation demonstrating measurement of peak inspiratory pressure (Ppk), plateau pressure (Pplat), and auto-PEEP. While delivering a constant inspiratory flow (not shown), airway pressure (Paw) increases to Ppk, the sum of airway resistive pressure and Pplat. Airway resistive pressure and Pplat are determined by an inspiratory pause during which inspiratory flow is temporarily stopped to eliminate airway resistive pressure, allowing Paw to fall from Ppk to Pplat. If inspiratory flow is set at 60 L/min, the resistance pressure drop equals airway resistance (Raw) in units of cm H_2O /L/sec. An end-expiratory hold maneuver is performed to measure auto-PEEP. During this maneuver, Paw increases by the amount of auto-PEEP present. Note that end-inspiratory and end-expiratory hold maneuvers are performed on different breaths.

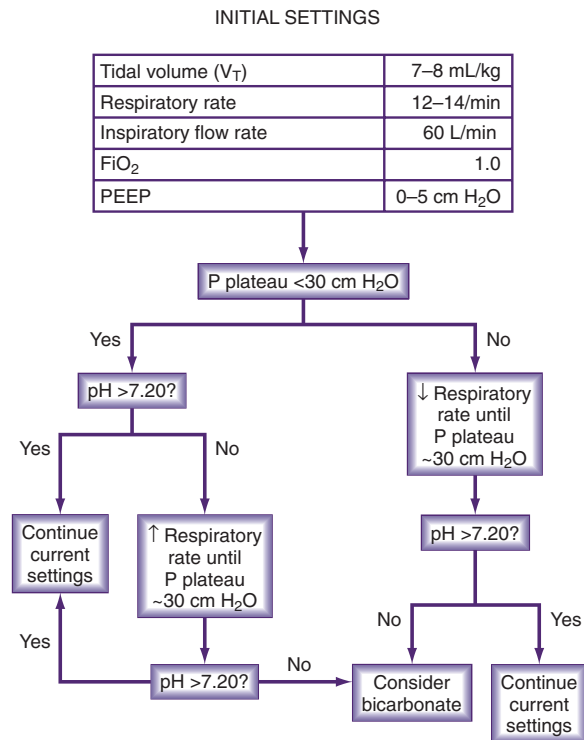

FIGURE 69-4 ■ Recommendations for initial ventilator settings and subsequent ventilator adjustments based on Pplat (end-inspiratory plateau pressure) and arterial pH in patients with severe asthma exacerbation.

tolerated. Anoxic encephalopathy and myocardial dysfunction are contraindications to permissive hypercapnia because of the potential for hypercapnia to dilate cerebral vessels, decrease myocardial contractility, and constrict the pulmonary vasculature. Lowering the respiratory rate may not increase $Paco_2$ as much as expected if it decreases hyperinflation and lowers dead space. If hypercapnia results in a blood pH of less than 7.20 and the respiratory rate cannot be increased because of the Pplat limit, we consider an infusion of sodium bicarbonate, although this has not been shown to improve outcome. If Pplat is less than 30 cm H_2O and pH is less than 7.20, the respiratory rate can be safely increased until Pplat reaches the 30-cm H_2O limit. Of note, strategies aimed at lowering Pplat are also expected to lower auto-PEEP.

Whether this strategy decreases the risk of barotrauma is unknown. One study of barotrauma in patients mechanically ventilated with limited V_t and airway pressures included 79 patients with asthma.²⁴ Five of these patients (6.3%) developed barotrauma. Tidal volumes and airway pressures did not differ between patients with and without barotrauma.

Sedation and Paralysis

Sedation improves patient comfort and safety and patient-ventilator synchrony. In patients who may be extubated within hours, propofol is recommended because it can achieve deep sedation while allowing for rapid reversal after discontinuation. Benzodiazepines are less expensive alternatives but are associated with a less predictable time to awakening and delirium. To provide amnesia, sedation, analgesia, and a suppressed respiratory drive, an opioid can be added to either propofol or a benzodiazepine. Daily interruption of sedatives and analgesics helps avoid undue accumulation.

Paralysis is indicated when safe and effective mechanical ventilation cannot be achieved by sedation and analgesia alone. The drug of choice is cisatracurium, which is essentially free of cardiovascular effects, does not release histamine, and does not rely on hepatic and

FIGURE 69-5 ■ Pressure-time tracings before and after successful administration of a bronchodilator. Note the drop in both airway resistive pressure and end-expiratory plateau pressure (Pplat), reflecting increased airway diameter and decreased lung inflation, respectively.

renal function for clearance. Paralytics have been associated with additional complications including myopathy, venous thromboembolism, and ventilator-associated pneumonia and should be discontinued as soon as possible.

Use of Bronchodilators During Mechanical Ventilation

Controlled trials are needed to inform the optimal use of bronchodilators in intubated patients and to provide evidence for or against current recommendations. Intubated patients generally require higher drug dosages to achieve a clinical effect. This may reflect the refractory nature of these patients or inadequate dose or delivery. Whether bronchodilators are administered by metered-dose inhaler (MDI) or nebulizer, patient-ventilator synchrony helps to optimize delivery. When MDIs are used during mechanical ventilation, a spacing device on the inspiratory limb of the ventilator is mandatory. When nebulizers are used, they should be placed close to the ventilator, and in-line humidifiers should be stopped during treatments. Dropping the inspiratory flow rate during nebulization helps minimize turbulence, but this strategy may worsen the extent of hyperinflation and should be time-limited.

Regardless of whether an MDI with spacer or nebulizer is used, higher drug dosages are required, and there should be a measurable fall in the peak-to-pause airway pressure gradient after bronchodilator delivery (Fig. 69-5). If no measurable drop in airway resistance occurs, then the patient may be refractory to bronchodilators, the delivery and/or dose of drug may be suboptimal, or there is another cause of fixed elevated airway resistance such as a kinked or plugged endotracheal tube.

Other Considerations

Rarely, the above management strategies fail to stabilize the patient. In these situations, general anesthetic bronchodilators may reduce peak pressures and $Paco_2$, but these agents are associated with hypotension and arrhythmias, and their benefits are short lived. Heliox delivered through the ventilator circuit may also decrease the peak pressure and $Paco_2$, but its use requires significant institutional expertise and planning. Limited evidence supports the use of mucolytic agents and even bronchoscopic lavage to help clear tenacious secretions. Importantly, a growing body of evidence demonstrates the successful use of extracorporeal life support in refractory cases with life-threatening DHI or respiratory acidosis despite optimal pharmacologic and ventilator management.

Extubation

Extubation criteria have not been validated for patients with acute asthma. One approach is to perform a spontaneous breathing trial

once Paco_2 normalizes without significant hyperinflation, airway resistance is $<20 \text{ cm H}_2\text{O/L/sec}$, mental status is acceptable, oxygen requirements are not excessive, PEEP is $\leq 5 \text{ cm H}_2\text{O}$, hemodynamics are stable, and secretions are not excessive. Patients with labile asthma may meet these criteria quickly after intubation; more commonly, 24 to 48 hours of treatment are required. After extubation, observation in an ICU is recommended for an additional 12 to 24 hours.

KEY POINTS

1. Failure to achieve control in the outpatient arena underlies many asthma exacerbations.
2. Severe exacerbations are characterized by diaphoresis, upright positioning, inability to speak in long sentences, use of accessory muscles, a widened pulsus paradoxus, and normo- or hypercapnia. Altered mental status, paradoxical breathing, bradycardia, and a quiet chest warn of imminent respiratory arrest.
3. Acutely ill asthmatics respond variably to inhaled β -agonists. Frequent (or continuous) administration of albuterol is required in refractory patients. Addition of ipratropium bromide to albuterol may confer additional benefit in patients with severe attacks.
4. Systemic steroids are indicated for severe asthma exacerbations.
5. Limited data support the use of noninvasive ventilation (NIV) to decrease inspiratory work of breathing in select patients.
6. Postintubation hypotension suggests inadequate expiratory time causing lung hyperinflation and decreased cardiac preload. A trial of apnea or hypopnea is both diagnostic and therapeutic in this setting. Tension pneumothorax is a concern in this clinical setting.
7. During mechanical ventilation, prolong the expiratory phase by setting low minute ventilation and an adequate inspiratory flow rate. Assess lung hyperinflation by measuring plateau pressure; if necessary, accept moderate hypercapnia to decrease lung hyperinflation.
8. Avoid prolonged paralysis and sedation during mechanical ventilation.
9. Establish a program to assess and achieve asthma control at the time of discharge to help prevent future exacerbations.

POSTEXACERBATION MANAGEMENT

The importance of education, adherence to controller agents, environmental control, and close follow-up cannot be overstated. Patients who have experienced severe asthma exacerbations are at risk for subsequent attacks and asthma-related death. In this regard, a tri-society task force report provides recommendations for antiinflammatory treatment after discharge and follow-up after acute asthma episodes.^{25,26}

Chronic obstructive pulmonary disease (COPD) is a major cause of death and disability worldwide and is one of the most common reasons for intensive care unit (ICU) admission. Several monographs review this complex disorder in some detail.^{1,2} The intensivist's view of COPD is predominantly physiologic, focusing on the impact of the disrupted lung function on the individual's normal homeostatic mechanisms. Although many important insights that have shaped our understanding of COPD have come from ICU studies, other aspects of this disorder must be considered if a rational approach to COPD management is to be developed.

Access to ICU care for sick COPD patients remains relatively inequitable among different healthcare systems. In North America and parts of Western Europe, most patients are offered ICU care, but in other relatively developed healthcare systems (e.g., in the United Kingdom), this is not the case. Even physicians in the same healthcare system differ significantly in their selection of patients for ICU referral.³ These choices may be influenced by local resource availability, but they are also conditioned by the pessimistic view of the outcome achievable with this treatment intervention. However, poor response to treatment in the ICU is not universal, and extended periods of mechanical ventilation are not invariably required to manage patients with COPD⁴ successfully. Nevertheless, intensivists often take a particularly bleak view of the prognosis of COPD patients compared with others entering their units. In one prospective study, intensivists estimated the survival of the sickest COPD patients to be 10% at 180 days post admission, when in fact it was 40%.⁵ In a survivor population after mechanical ventilation, 96% were happy to have received ventilator support, despite their continuing physical problems.⁶ Survival appears to relate more to the severity of the acute illness, such as higher acute physiology scores, longer preceding hospital length of stay, the level of consciousness, and cardiac dysrhythmia, rather than premorbid factors such as age, forced expiratory volume (FEV₁), and functional capacity.⁷ Clearly, decisions about ventilator support should not be made in the emergency department without sufficient medical information or a proper discussion with the family, something that was seen in only a minority of cases in the 2014 England and Wales national audit hospitalizations due to COPD.⁸

DEFINITION AND NATURAL HISTORY

Although the most appropriate definition of COPD has been debated, it has less of an impact in the context of ICU care, where acute hospitalization is usual only in cases of severe and well-established disease. The currently favored definition, developed by the Global Initiative for Chronic Obstructive Lung Disease (GOLD), is as follows:

*"Chronic obstructive pulmonary disease (COPD), a common preventable and treatable disease, is characterized by persistent airflow limitation that is usually progressive and associated with an enhanced chronic inflammatory response in the airways and the lung to noxious particles and gases. Exacerbations and comorbidities contribute to the overall severity in individual patients."*⁹

The emphasis here is on incompletely reversible airflow obstruction that is persistent and progressive though the importance of comorbidity and exacerbations is increasingly recognized; the latter being the

usual contact point for intensive care specialists. Symptoms and disability usually parallel these processes, although some individuals can apparently cope with a severe degree of airflow limitation without seeking medical assistance. Such patients finally present to the emergency room when they develop a severe exacerbation of COPD. In this situation, it is wisest to offer ventilatory support until the patient has at least had a chance to improve with conventional medical therapy. More common is a patient whose progressive illness is accompanied by repeated exacerbations, events that identify an accelerated decline in both lung function and health status.^{10,11} Such patients have often been hospitalized previously, and their response to treatment is usually clearly established.

The usual inhaled particles or gases that produce COPD are a complex mixture of hydrocarbons and particulates derived from tobacco smoke. These are the principal causes of COPD in the United States and Western Europe,¹² although other factors, such as poor lung function during childhood and childhood respiratory illness, bronchial hyperresponsiveness, self-reported asthma, and low birth weight, may also be important.¹³ The associated inflammatory changes, which persist when smoking stops,^{14,15} are thought to explain the airway and parenchymal destruction, as well as fibrosis within the lung.

The natural history of COPD explains why the number of patients presenting for ICU care has not diminished in the last three decades as might be expected, given the overall reduction in tobacco consumption in Western countries. This is illustrated by the classic study of Fletcher and Peto, which has now been confirmed by longitudinal data from the Framingham study^{16,17} (Fig. 70-1). Although the rate of decline of lung function is reduced in individuals who stop smoking, the lung function that is already lost can never be regained. Moreover, even if the rate of decline of lung function returns to normal, these patients are still more likely to experience disability as they age. Thus, in an aging population that contains many former smokers, a significant number will still develop complications of COPD that require ICU care. The important role of comorbidities in COPD has now been recognized.^{18,19} Most patients with significant symptoms due to COPD have at least one if not multiple comorbid diseases, especially cardiovascular problems.²⁰

PATHOLOGY

The pathologic features of COPD depend on the stage of the illness and the part of the lung examined.²¹ Central airways show mucous gland hypertrophy and goblet cell metaplasia, whereas more peripheral airways show variable combinations of smooth muscle hypertrophy, peribronchial fibrosis, luminal occlusion by mucus, and enlarged lymphoid follicles. Alveoli are often but not invariably enlarged by the loss of alveolar walls, with an attendant loss of support for the small non-cartilaginous airways in this region of the lung. There is evidence of persistent inflammation, with the presence of neutrophils in the airway lumen and macrophages in the airway wall. CD8⁺ T lymphocytes are more prominent in this response than in bronchial inflammation of an asthmatic type, although intermediate states appear to exist.²² Inflammatory cells are also present adjacent to breaks in the alveolar wall.²³ Overall, as the clinical and spirometric severity of the disease increases, so do the numbers of each cell population involved in the

FIGURE 70-1 ■ Natural history of chronic obstructive pulmonary disease and the effect of smoking cessation. Compared with lung function standardised to age 25, smokers show an accelerated rate of decline in forced expiratory volume (FEV_1), which returns to more normal values when they stop smoking. However, they are operating at a lower FEV_1 than predicted for their age, and the physiologic decline continues. This explains why older ex-smokers can present to the ICU with severe disease despite years of abstinence. (Adapted from Fletcher C, Peto R. The natural history of chronic airway obstruction. *BMJ* 1977;1(6077):1645-8.)

inflammatory process.²⁴ In addition, extraluminal lymphoid follicles develop containing $CD4^+$ lymphocytes, possibly reflecting a response to repeated infective exacerbations.²⁴ Recent work has linked elements of this host immune response to the lung microbiome assessed using DNA sequencing.²⁵ Data obtained during exacerbations, though limited, support an increased role for neutrophils and, surprisingly, eosinophils,²⁶ with ongoing trials examining blood eosinophil count as a biomarker to determine use of corticosteroids during COPD exacerbations.²⁷

■ PHYSIOLOGY

The pathologic changes described above combine to produce the characteristic diagnostic finding of reduced FEV_1 at a given lung volume, which is usually assessed on a time basis as an FEV_1 /forced vital capacity (FVC) ratio of less than 0.7. Technically, this should be 70% of the age-adjusted normal value for this ratio, as lung elastic recoil declines with age, even in healthy individuals.

COPD affects all aspects of lung function, but its primary impact is a change in lung mechanics. This is traditionally analyzed regarding the static (no flow) and dynamic (flow) properties of the respiratory system.²⁸ Since chest wall mechanics are believed to be normal in COPD (although they are seldom measured directly), changes in the pressure-volume characteristics of the respiratory system are determined by alterations in lung compliance, often attributed to the loss of elastic recoil due to emphysema. How large a role this plays in changes in tissue compliance is not known. The resulting steeper slope, early onset inspiratory plateau, and increase in end-expiratory lung volume are typical of the pressure-volume relationships in patients with COPD. Changes in end-expiratory lung volume and increases in residual volume change the chest wall geometry and favor a lower, flatter diaphragm, as well as a more horizontal rib cage. These changes, in turn, impair the inspiratory muscles' ability to develop pressure and increase the overall work of breathing.²⁹ Expiratory muscle activation is common in more severe COPD^{30,31} even at rest and provides a useful clinical marker of respiratory distress. The dynamics of the respiratory system are influenced by static properties but also differ significantly

between inspiration and expiration. Maximum inspiratory flow is affected by inspiratory resistance, as well as by the inspiratory muscles' ability to develop pressure (and thus indirectly by chest wall geometry). Maximum expiratory flow is influenced by expiratory pressure generation and, more importantly, by the onset of volume-related airflow limitation, best described by the maximum expiratory flow-volume loop. As lung volume falls during expiration, airways close or become flow limited. Thus, the flow at a specific lung volume is reduced. Although an assessment of flow (FEV_1) relative to total volume change during expiration (FVC) is useful in defining COPD, an assessment of tidal flow limitation is more helpful in determining the degree of dyspnea experienced by the patient.³² More attention is now being paid to the determination of expiratory flow limitations under tidal conditions. In the past, detection was difficult, involving invasive measurements or a reliance on body plethysmography, which tended to overestimate the incidence of tidal expiratory flow limitation. The development of the negative expiratory pressure test and, more recently, within-breath variation in respiratory system reactance has changed this.³³ The within-breath method assesses more breaths, is less prone to observer error, and is likely to be automated in the future for ICU application.³⁴

In general, the lower the FEV_1 , the greater the likelihood that expiratory flow limitation is present. However, some COPD patients are not flow limited on every breath and regulate their end-expiratory lung volume to try to minimize this. When respiratory drive rises (e.g., during exercise), during disease exacerbations, or when minute ventilation increases to maintain gas exchange during ventilator weaning, this resting variation in expiratory lung volume is likely to decrease. If expiratory flow and hence tidal volume are to increase, end-expiratory lung volume must rise, further increasing the work of breathing and the sensation of respiratory distress. This process, described as *dynamic hyperinflation*, has been clearly demonstrated during exercise and can be lessened by bronchodilator treatment that aids lung emptying.³⁵

In the ICU, patients have a high respiratory drive during weaning and adopt a rapid, shallow breathing pattern. Total respiratory muscle work increases, in part because of the increased operating lung volumes but also due to the presence of intrinsic positive end-expiratory pressure (PEEPi). This represents the pressure that must be developed to overcome residual expiratory driving pressure before inspiratory flow can begin.³⁶ What is clear is that the overall impairment of mechanical function in COPD is substantial and that both static and dynamic properties interact. This concept is best captured by the time constant of the respiratory system, which is the product of the total respiratory system resistance in compliance. This is greatly lengthened in COPD and helps explain why lung emptying is delayed and dynamic hyperinflation occurs. There is substantial evidence of regional inhomogeneity in more severe COPD. Differences in the regional time constants explain why COPD patients are prone to barotrauma during mechanical ventilation, despite seemingly acceptable peak inspiratory pressures, as well as why gas exchange can be quite disordered in this population.

Gas Exchange

Arterial hypoxemia is common in COPD but becomes clinically significant only when the partial pressure of oxygen in arterial blood (P_{aO_2}) falls below 60 mm Hg, a problem largely confined to patients with an FEV_1 below 35% of their predicted value. It arises predominantly due to ventilation-perfusion mismatching, often worsens during exercise, and is readily corrected by a small increase in the inspired oxygen concentration, unless the situation is made worse by secretion retention or severe pneumonia.³⁷ Arterial hypercapnia is seen in some but not all hypoxemic patients who are clinically stable, but it is more frequent, at least temporarily, in hospitalized individuals.³⁸ A combination of ventilation-perfusion mismatching due to an increase in physiologic dead space and a degree of effective alveolar hypoventilation explains this phenomenon. Acute increases in the partial pressure of arterial carbon dioxide (P_{aCO_2}) precipitate respiratory acidosis, a more

reliable guide to prognosis and the need for ventilation than the PaCO_2 itself.^{39,40}

Control of Breathing

Despite years of study, there is no conclusive evidence that ventilatory control is abnormal in COPD patients. However, the response to sustained mechanical loading appears to be variable in healthy subjects⁴¹ and may explain why some individuals adopt the breathing patterns they do. Traditional techniques of studying respiratory control, which involve stimulation with exogenous CO_2 or nitrogen, suggest that respiratory drive is reduced. However, studies using mouth occlusion pressure techniques or recording the electrical activation of inspiratory muscles suggest that respiratory drive is elevated, even in those COPD patients who tolerate relatively high levels of CO_2 .^{42–44} Studies of breathing patterns have been more instructive. In general, the lower the tidal volume, the higher the PaCO_2 .⁴⁵ This is because the ratio of dead space (it is a fixed, predominantly anatomically determined volume) to tidal volume increases as the latter is reduced. Small tidal volumes are accompanied by an increased respiratory frequency to maintain the somewhat higher-than-normal level of minute ventilation. The resulting shortening of inspiratory time is also associated with hypercapnia.⁴⁵ The system appears to be regulated to minimize peak inspiratory pressure generation, even at the cost of impaired gas exchange. There are theoretical reasons for believing that this is both energy efficient and likely to minimize the occurrence of inspiratory muscle fatigue.⁴⁶ This also explains the usefulness of rapid, shallow breathing as an index of weaning failure when neuromechanical coupling in the respiratory system is under considerable stress.⁴⁷

Pulmonary Circulation

In the past, considerable attention was paid to the determination of pulmonary artery pressure in COPD patients, but this is now thought to be less important. Undoubtedly, pulmonary artery pressure increases by day and at night⁴⁸ in hypoxemic COPD patients, reflecting a combination of hypoxic vasoconstriction and pulmonary vascular remodeling. How important this is in the daily limitation of exercise reported by these patients is not clear, but it is known that treatment with domiciliary oxygen prevents disease progression⁴⁹ and may even reduce pulmonary artery pressure. More specific attempts at therapy, including treatment with vasodilators, phosphodiesterase enzyme type V (PDEV) inhibitors, and nitric oxide (studied inside and outside the ICU) have been unsuccessful, usually resulting in unacceptable worsening of ventilation-perfusion mismatching.⁵⁰ Further investigation and treatment is reserved for the small number of patients (<5%) who have severe pulmonary hypertension that is disproportionate to their COPD severity⁵¹ with an assessment of pulmonary hypertension now not part of a routine evaluation in COPD patients, but its occurrence is important to note when interpreting changes in central venous pressure in instrumented patients.

SYSTEMIC EFFECTS

There is good evidence that systemic (extrapulmonary) factors are important in COPD. Patients with a reduced body mass index die sooner than better-nourished individuals with a similar degree of pulmonary function impairment, although those who can gain weight fare better.⁵² There are data to show that peripheral muscle function is impaired,⁵³ fiber type is altered,⁵⁴ and exercise is associated with increased oxidative stress.⁵⁵ The earlier concept of a specific COPD myopathy has now largely been abandoned, as the major burden falls on the lower limb muscles, with preserved function in the upper limb muscle groups. This likely reflects inactivity, which is worse in those with exacerbated COPD.⁵⁶ Weakness of the quadriceps muscle is an independent guide to a poor prognosis.⁵⁷ In contrast, while the wealth of circulating biomarkers in COPD appear to relate to mortality, they have contributed little to practical management so far.⁵⁸

EXACERBATIONS

An *exacerbation* of COPD is currently defined as sustained worsening of the patient's condition from the stable state, beyond normal day-to-day variation, that is acute in onset and necessitates a change in regular medication.⁹ The key feature is the sustained change from usual daily symptoms. The operational requirement for a change in treatment is more arbitrary but is almost always present in patients referred to ICU care. Disease exacerbation is the principal cause of ICU admission with COPD, and patients commonly have or are at risk of developing significant *respiratory failure*, defined as a PaO_2 below 60 mm Hg with or without an increase in PaCO_2 .⁵⁹ The most common causes of an exacerbation are listed in Table 70-1. Viral and bacterial infections are both relevant,⁵⁴ with rhinoviruses commonly reported in most series; *Hemophilus influenzae* and *Streptococcus pneumoniae* are the principal microbial pathogens.^{60,61} Some patients, particularly those with a regular cough and green sputum production, develop persistent lower respiratory tract colonization, making the interpretation of qualitative microbiology difficult.⁶²

Not all exacerbations of COPD have an infectious precipitant, and changes in the degree of atmospheric pollution can precipitate events in some patients.⁶³ The frequency of exacerbation rises as spirometric impairment worsens⁶⁴ and evidence from a large, longitudinal study shows that for an individual, frequency of exacerbation is remarkably stable year on year.⁶⁵

The physiologic consequences of increased airflow obstruction secondary to increased inflammation within the bronchial tree are summarized in Fig. 70-2. Whatever the precipitant, the key event appears to be a change in lung mechanics. Previously, attention focused on alterations in respiratory system resistance, but more recent data emphasize that airway narrowing and closure may be more important, particularly by producing changes in operating lung volumes (see earlier discussion). Observations in patients recovering from hospitalized exacerbations have shown progressive improvements in respiratory system reactance (a measure of inspiratory resistance and flow limitation) together with reductions in end-expiratory lung volume that are most evident in patients reporting less dyspnoea.⁶⁶

Pneumonia is an important reason for hospitalization in COPD, is more frequently seen in these patients than in others, and is associated with more severe outcomes.⁶⁷ Pneumonia is diagnosed more frequently in patients taking the inhaled corticosteroid, fluticasone propionate,⁶⁸ especially older patients with worse airflow obstruction.⁶⁹ These pneumonias are not necessarily associated with poor outcome in terms of mortality or health status⁶⁸ and are not seen with all types of inhaled corticosteroids.^{70,71} At present, the benefit of inhaled corticosteroid treatment, especially combined with a long-acting inhaled bronchodilator, outweighs the apparent risk of increased pneumonia events.

TABLE 70-1

Causes of Chronic Obstructive Pulmonary Disease Exacerbation

NEW INFECTION:

Bacterial (*Hemophilus influenzae*, *Streptococcus pneumoniae*, *Moraxella catarrhalis*)

Change in an existing strain (e.g., *H. influenzae*)

Viral (influenza, rhinovirus, respiratory syncytial virus)

ATMOSPHERIC POLLUTION:

Sulfur dioxide, oxides of nitrogen

TEMPERATURE CHANGE:

Often related to pollution episodes

INTERCURRENT ILLNESS*:

Pneumonia, pulmonary embolus, pneumothorax

POSTOPERATIVE:

Especially after upper abdominal surgery

*Clinical presentation is dominated by the primary illness, but respiratory failure can occur.

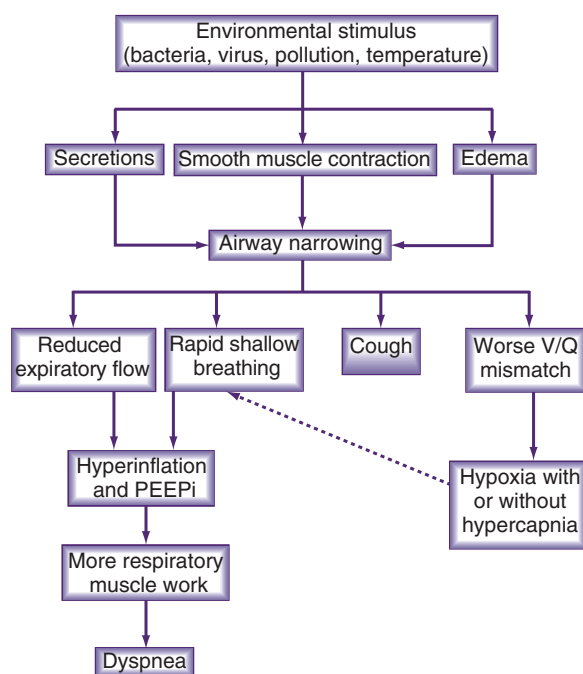

FIGURE 70-2 ■ Schematic of principal physiologic changes that accompany an exacerbation of chronic obstructive pulmonary disease. Note that deterioration in one area tends to produce worsening in other areas and leads to a downward spiral in functional abnormality. PEEPi, intrinsic positive end-expiratory pressure; V/Q, ventilation-perfusion.

TABLE 70-2

Indications for Invasive Mechanical Ventilation

| |
|---|
| Severe dyspnea, with use of accessory muscles and paradoxical abdominal motion |
| Respiratory frequency > 35 breaths/min |
| Life-threatening hypoxemia ($\text{PaO}_2 < 40$ mm Hg or $\text{PaO}_2/\text{FiO}_2 < 200$ mm Hg) |
| Severe acidosis ($\text{pH} < 7.25$) and hypercapnia ($\text{PaCO}_2 > 60$ mm Hg) |
| Respiratory arrest |
| Somnolence, impaired mental status |
| Cardiovascular complications (hypotension, shock, heart failure) |
| Other complications: metabolic abnormalities, sepsis, pneumonia, pulmonary embolism, barotrauma, massive pleural effusion |
| Noninvasive positive pressure ventilation failure (or exclusion criteria) |
| FiO_2 , inspired oxygen fraction; PaCO_2 , partial pressure of carbon dioxide in arterial blood; PaO_2 , partial pressure of oxygen in arterial blood. |

■ INTENSIVE CARE UNIT REFERRAL

The need for ventilatory support is the primary reason for ICU referral among COPD patients. Although the various indications for mechanical ventilation (Table 70-2) vary in frequency from institution to institution, they represent the most common causes of ICU admission. Before referring a patient for ICU care, and especially for any form of ventilatory support, it is important to determine what degree of intervention is appropriate.

■ PRINCIPLES OF TREATMENT

Four general principles guide the management of COPD patients presenting acutely to the ICU, and each should contribute to shortening the duration of illness and stabilizing the patient physiologically until

either the natural course of the disease or the effects of therapy lead to its resolution.

Treat Precipitating Factors

Bacterial infection is the most common reason for ICU admission in COPD patients. There is now good evidence that antibiotics shorten the symptomatic period, even when patients are treated with corticosteroids⁷²; when given early, antibiotics are associated with lower mortality, fewer episodes of intubation, and shorter hospital stays.⁷³ Radiographic evidence of pneumonia likely requires a broadening of the antibiotic spectrum, but whether the infection is confined to the airways or involves the alveoli, antibiotic therapy should follow locally established guidelines designed to minimize the development of resistance within the ICU and to address known patterns of drug resistance in the community and the hospital. Broad-spectrum penicillins or, more commonly, cephalosporins are usually recommended, often with an intravenous macrolide. Colonization with methicillin-resistant *Staphylococcus aureus* is a frequent problem and requires particular vigilance in the selection of antibiotics. Likewise, excessive use of broad-spectrum agents can produce superinfection, such as *Clostridium difficile* diarrhea.

The 2009-10 H1N1 influenza A pandemic made the role of antiviral drugs clearer, and a meta-analysis showed that the early use of neuraminidase inhibitors (within 48 hours) was associated with a lower mortality rate, although this was not specific for acutely ill COPD patients.⁷⁴ In fact, the pandemic infection was not a particular problem for COPD patients, possibly reflecting prior partial immunity,⁷⁵ but if this virus is diagnosed, the use of antivirals such as oseltamivir is prudent. Similar considerations apply to other viral pneumonias.

Reduce Lung Volume and Increase Expiratory Flow

Agents that improve lung emptying, commonly by increasing airway caliber or preventing airway closure, interfere with the vicious circle of pulmonary hyperinflation. This has been demonstrated in stable patients using exercise as a model of hyperinflation,³⁵ but the data in spontaneously breathing COPD patients during exacerbations are much less satisfactory. Nonetheless, treatment with regular but high doses of short-acting nebulized β -agonists, such as albuterol or ipratropium (2.5-5 mg or 250-500 μg , respectively), is usually recommended. There is no clear evidence that one drug is better than the other,⁷⁶ and combination therapy is commonly used. Intravenous theophylline, or one of its derivatives, is often added to these regimens but is no more effective than a placebo infusion.^{77,78}

Reduce Pulmonary Inflammation

Several randomized, controlled trials have shown that oral corticosteroids shorten the duration of hospitalization and accelerate the improvement of postbronchodilator FEV_1 during an exacerbation of COPD.^{79,80} Patients randomized to treatment with oral corticosteroids were less likely to relapse during the subsequent month and showed a number of other benefits, although these did not always reach statistical significance.⁸¹ There is little detriment from giving a short (5-day) course of oral corticosteroids rather than a long (14-day) course and overall steroid dose is dramatically reduced.⁸² This has been confirmed in a meta-analysis.⁸³ In the ICU, corticosteroid treatment is often given peremptorily to patients on mechanical ventilation. Two recent studies have yielded conflicting results with one study using 10 days of tapering dose methylprednisolone showing a shorter period of ventilation and reduced noninvasive ventilation (NIV) failure,⁸⁴ while a larger study used up to 10 days of a higher dose prednisolone, showing no benefit but higher rates of hyperglycaemia.⁸⁵ A retrospective review of a dose of systemic corticosteroids used within the first 48 hours of admission to the ITU showed better lower ITU and hospital length of stay, shorter period of ventilation, less use of insulin,

and fewer fungal infections in COPD patients given less than 240 mg methylprednisolone per day.⁸⁶ Caution should be exercised because, in addition to the above effects, these individuals are often at risk for relatively acute-onset corticosteroid myopathy.⁸⁷ In the absence of a large randomized controlled trial and recognizing that 94% of patients in the retrospective review were prescribed systemic corticosteroids, it appears appropriate to use lower doses for shorter periods.

Manage Gas Exchange

It is relatively easy to improve oxygenation in an uncomplicated exacerbation of COPD.⁸⁸ Raising the inspired oxygen concentration to 28% to 35% is usually sufficient to achieve a P_{aO_2} greater than 90 mm Hg. However, this can be accompanied by an undesirable increase in P_{aCO_2} , with its accompanying respiratory acidosis. Such an increase in P_{aCO_2} impairs respiratory muscle function, at least during loaded breathing,⁸⁹ and often precedes more serious clinical deterioration, including impairment of consciousness. The reasons for this effect have been debated for many years, with some advocating a reduction in the respiratory drive from the carotid chemoreceptors and others citing a worsening ventilation-perfusion match as the cause.⁸⁸ Each view has evidence to support it, but the actual cause is likely a combination of both problems, with ventilation-perfusion mismatching being particularly important in severely ill patients and hypoventilation playing a larger role in those not yet sick enough to require intubation.⁹⁰

Although the phenomenon of oxygen-induced hypercapnia has been recognized for decades, it remains a real problem. In one large center in the United Kingdom, 34% of individuals exhibited evidence of oxygen-induced hypercapnia.⁴⁰ The use of high-flow oxygen in the emergency room is widespread, as is the false sense of security provided by a high oxygen saturation. Many intensivists have legitimate concerns about the failure to adequately oxygenate COPD patients with compromised circulation, along with the attendant risk of unanticipated mortality. However, the solution is to consider carefully the risks of excessive or insufficient oxygen in a given individual, rather than to adhere slavishly to one view or the other. Patients whose problems are predominantly due to COPD and who have a normal hemoglobin and preserved cardiac output can maintain adequate tissue oxygen delivery with an oxygen saturation as low as 85%, and they will do quite well if an arterial oxygen saturation (S_{aO_2}) of 90% to 93% is maintained. The modest increase in inspired oxygen needed to achieve this (often 24%-28%) is accompanied by less hypercapnia and may avoid the need for ventilatory support. However, if cardiac output is impaired (reduced blood pressure, poor peripheral circulation) or tissue metabolic demands are increased (e.g., in sepsis secondary to pneumonia), a higher S_{aO_2} will be required to ensure sufficient oxygen delivery. In this case, the consequences of any resultant hypercapnia, including the need for ventilatory support, must be accepted.

■ NONINVASIVE VENTILATION

This topic is reviewed in detail in Chapter 49, but some key issues relevant to COPD are worth emphasizing. Many of the data supporting the use of NIV were obtained in patients with hypercapnic respiratory failure due to COPD exacerbation, and several excellent reviews have analyzed these data.⁹¹⁻⁹³

NIV has a number of potentially beneficial effects in COPD. Intuitively, it seems reasonable to expect that it would increase tidal volume, improve CO_2 elimination, and hence reduce respiratory drive. Studies of gas exchange using a multiple inert gas elimination methodology confirmed that CO_2 elimination is increased, but overall ventilation-perfusion mismatch is not altered during NIV.⁹⁴ A more important effect is the unloading of the respiratory muscles, which are often close to fatigue conditions in severe episodes of respiratory failure. By assuming some of the additional work required to overcome intrinsic PEEP, NIV directly reduces the drive to breathe and the respiratory rate falls, which is a good prognostic feature.⁹⁵ Data from randomized, controlled trials suggest that there is a mean fall of 3.1 breaths per

TABLE 70-3

Efficacy of Noninvasive Ventilation Compared with Usual Care

| OUTCOME | NUMBER OF PATIENTS STUDIED | RELATIVE RISK (95% CONFIDENCE INTERVAL) | NNT |
|-------------------|----------------------------|---|-----|
| Treatment failure | 529 | 0.51 (0.38-0.67) | 5 |
| Death | 523 | 0.41 (0.26-0.64) | 8 |
| Intubation | 546 | 0.42 (0.31-0.59) | 5 |
| Complications | 143 | 0.32 (0.18-0.56) | 3 |

NNT, number needed to treat—the number of patients who must be treated to prevent this outcome in one individual.

minute (95% confidence interval: 4.3 to 1.9) with the institution of NIV in COPD patients.⁹³ This allows more effective emptying of the lungs and less dynamic hyperinflation. The resulting improvement in the intensity of breathlessness is usually a much earlier sign of successful NIV treatment in COPD than a change in blood gas tensions, which often lag behind evidence of clinical improvement.

Evidence-based reviews provide a reasonable series of recommendations based on the relative effectiveness of NIV. Key points, including the number of patients needed to be treated to prevent one significant event or complication, are shown in Table 70-3.⁹¹ NIV is associated with less treatment failure, lower mortality, fewer complications, and a lower intubation rate compared with conventional medical treatment. It reduces ICU or hospital stay by approximately three days and favorably influences gas exchange. With NIV, pH increases by a mean value of 0.03 (0.02-0.04), P_{aCO_2} falls by 3 mm Hg (5.9-0.23 mm Hg), and P_{aO_2} rises by 2 mm Hg (−2 to +6 mm Hg). The lower rate of nosocomial pneumonia associated with NIV is a particular advantage. No benefit was seen from the use of helium-oxygen mixture with NIV compared with oxygen alone.⁹⁶

Treatment failure, which occurs in 10% to 15% cases in many US hospitals,^{97,98} reflects an inability to adapt to NIV or progression of the underlying disease. Data suggest that patients likely to subsequently fail with NIV can be prospectively identified by a high blood sugar upon admission (irrespective of having diabetes), a raised respiratory rate, or a high APACHE 2 score. All of these variables are relatively effective predictors of risk, but combining them increases their discriminant power.⁹⁵ A more recent study confirmed the importance of acute physiology (APACHE 2 score) but also highlighted a higher failure rate and mortality if the individual had cancer.⁹⁷ In addition to its role in the acute phase of respiratory failure, NIV can be valuable as a “bridge” in helping patients wean from intermittent positive pressure ventilation. In an important multicenter prospective trial, Nava and colleagues randomized people who had failed a T-piece weaning trial to either NIV or further mechanical ventilation.⁹⁹ NIV was associated with fewer days of ventilatory support (10.2 versus 16.6, respectively), shorter ICU stay (15.1 versus 24 days), less nosocomial pneumonia, and better 60-day survival (92% versus 72%). These results were achieved in a unit with experience in NIV. The generic use of weaning by NIV has proven less successful, particularly if patients have a significant cardiac disease or established acute respiratory distress syndrome (ARDS).¹⁰⁰ However, further data from Spain have confirmed the value of this approach in hypercapnic patients limited primarily by COPD.^{101,102} When early extubation followed by NIV was compared with continued mechanical ventilation in a Cochrane review, the outcomes were superior in all areas.

Mechanical Ventilation

Mechanical ventilation should be considered when NIV is not appropriate or has failed. Patients with a pH below 7.25 are more likely to require this therapy, although most physicians now offer a trial of NIV

TABLE 70-4 Modes of Ventilation

| MODE | METHOD | COMMENT |
|--|--|---|
| Assist-control | Preset tidal volume, patient triggered with backup rate | Patient still performs substantial work of breathing; dynamic hyperinflation worsens this |
| Spontaneous intermittent mandatory ventilation | Preset number of breaths of a preset volume—patient does the rest | Patient still makes an effort during part of machine breath—involves more patient work, especially at low respiratory rates |
| Pressure support ventilation | Pressure set to augment each inspiration—tidal volume depends on patient effort, pulmonary mechanics, and pressure applied | Basis of noninvasive ventilation therapy; pressure titrated to a respiratory rate below 27 breaths/min; asynchrony with machine breaths a problem at high pressures |
| Proportional assist ventilation | Flow and volume generated proportional to patient effort | Experimental technique; requires accurate measurement of elastance and resistance + an intact drive to breathe; proven effective in COPD patients |

unless the patient is hemodynamically unstable or the treatment is contraindicated. Persistent significant hypoxemia despite treatment, hypotension, and impaired mental state are all predictors of imminent respiratory arrest and the need for intubation and institution of mechanical ventilation.

Ventilation Strategies

A wide range of ventilation strategies have been advocated for use in COPD, each with its proponents. However, none have shown a clear advantage over its competitors. Familiarity with the equipment in the context of COPD patients is probably more important than the relatively minor differences between ventilator modes. The most commonly used approaches, together with their proposed advantages, are summarized in [Table 70-4](#).

Assisted Ventilation and Weaning

As acidosis resolves and oxygen requirements fall, it is possible to reduce the degree of sedation and allow the patient to make some contribution to ventilation before weaning. Several modes of ventilatory support are available in these circumstances, and again, there is no specific advantage of one over another.^{103,104} There is an impression, however, that reliance on spontaneous intermittent mandatory ventilation prolongs subsequent weaning. Although not universally accepted, there are good data supporting the use of spontaneous breathing trials in clinically stable COPD patients to determine when they are ready to wean.¹⁰⁴⁻¹⁰⁶ The ability to sustain ventilation in the absence of increasing CO₂, worsening acidosis, or clinical distress (reflected by an increase in blood pressure, heart rate, or restlessness) is agreed to be a predictor of future weaning success. Although COPD patients are less likely to achieve these goals as early as other ICU patients, the reintubation rate in those who do meet these criteria is low.^{105,106} Unfortunately, breathing through the ventilator on a continuous positive airway pressure (CPAP) circuit may be associated with significant increases in inspiratory resistance,¹⁰⁷ and it is sensible to use pressure support to offset some of this additional respiratory work. This reflects the necessity of identifying patients who can be weaned using the ventilator

TABLE 70-5 Criteria for Weaning Failure

Increasing hypercapnia or worsening hypoxemia (<55 mm Hg)
pH < 7.32
Increased respiratory rate > 35 breaths/min
Increase in heart rate or blood pressure by 20% of baseline
Agitation, sweating, or impaired consciousness

alone and those who need more prolonged support. In the latter circumstance, weaning supported by NIV is particularly helpful.

A variety of predictors of weaning success have been developed to try to identify when successful weaning will occur. Unfortunately, none have proved entirely reliable and relatively few have been assessed prospectively. An empirical approach based on the criteria listed in [Table 70-5](#) is widely used. An aggressive policy toward weaning is justified in COPD patients because an inability to wean is invariably associated with a worse prognosis and prolonged ventilation.

NONVENTILATORY ISSUES

Therapy employed in spontaneously breathing patients is still required in those undergoing mechanical ventilation. High-dose nebulized bronchodilators are commonly used, alone and in combination,^{108,109} although it is important to pay attention to the details of drug delivery. If a metered dose inhaler is used instead, it should always be given with some form of spacer device for the same reason. Parenteral corticosteroids are commonly administered. This is not without hazard, particularly because of the real risk of myopathy, and this was reviewed earlier in the chapter.

Clearance of secretions is important in ventilated patients, and it is essential that the patient's hydration state be maintained. Whether specific mucolytic drugs such as *N*-acetylcysteine are helpful is unclear, and no good scientific studies to support or reject their use are available.

PROGNOSIS

The prognosis following an exacerbation of COPD is better than the gloomy outlook proposed by some physicians. Nonetheless, patients who experience exacerbations appear to have a more severe clinical course than those who do not, and they report a worse overall quality of life.¹¹⁰ Mortality after an ICU admission is significant, at least in recent North American series, 7.4% in patients treated with NIV and 16.1% in those treated with mechanical ventilation.⁹⁸ However, some groups have reported worse and individuals with COPD treated with long-term oxygen therapy who failed NIV and received mechanical ventilation had 23% in-hospital mortality and 45% 1-year mortality with 27% discharged to nursing care.¹¹¹ Patients with a low FEV₁, significant comorbidity, and a particularly poor performance status at home have the worst outlook.¹¹² These factors should be considered when decisions about the requirement for ventilatory support are made. However, as noted already, the physician's view of the very sick COPD patient can be unduly pessimistic. Exacerbations leave patients relatively immobile, and this has now been confirmed objectively.⁵⁶ The initial encouraging data concerning potential benefits from early rehabilitation have not been confirmed in a large RCT of patients hospitalized due to an acute COPD exacerbation but not ventilated. The intervention was robust and included aerobic and resistance training, neuromuscular electrical stimulation, a written self-management plan, and education. However, no reduction in readmission was seen in the following year.¹¹³

Changes in clinical practice continue to improve the outlook for COPD patients. The impact of NIV on their acute care has been enormous, as has closer adherence to evidence-based recommendations across the field of intensive care,¹¹⁴ something about which both practitioners and their patients can feel proud.

KEY POINTS

1. The prognosis of patients with chronic obstructive pulmonary disease (COPD) admitted to the ICU is better than commonly believed.
2. The burden of symptomatic COPD is likely to rise for several decades more, despite effective smoking cessation programs in many countries.
3. Small changes in forced expiratory flow are associated with significant impairment in lung mechanics, particularly airway closure and dynamic hyperinflation, and worse gas exchange.
4. Common upper respiratory tract pathogens and respiratory viruses precipitate most exacerbations of COPD. Treatment aimed at these agents is useful, but it is not as important as improving lung emptying and maintaining gas exchange until the acute insult resolves.
5. Oral and intravenous corticosteroids shorten the duration of an exacerbation and reduce the risk of relapse. However, high-dose treatment beyond 2 weeks provides no advantage and actually poses a risk, especially in ventilated patients.
6. Maintaining oxygenation is relatively easy, but there are risks of carbon dioxide retention and acidosis if high-flow oxygen is administered. An oxygen saturation between 91% and 93% ensures adequate tissue oxygen delivery if the cardiac output is stable.
7. Respiratory acidosis is a poor prognostic marker in COPD exacerbations and a strong indicator of the need for assisted ventilation.
8. Unless contraindicated, noninvasive ventilation (NIV) is the safest and most effective way of managing acute respiratory failure. More acidotic patients should be managed in an ICU with the option of endotracheal intubation and mechanical ventilation if NIV fails.
9. COPD patients meet conventional weaning criteria less frequently than other ICU patients do, but they are more likely to wean successfully when they do meet the criteria.
10. Seriously ill COPD patients should be encouraged to make advance directives, particularly after an ICU admission involving any form of ventilatory support.

Venous thromboembolism (VTE) comprises both deep venous thrombosis (DVT) and pulmonary embolism (PE). Intensive care unit (ICU) patients often have unique diagnostic and treatment issues related to VTE. Accurate risk stratification remains a critical component of the initial evaluation and treatment of patients who have acute PE. The primary treatment options for PE include anticoagulation and thrombolytic therapy, while catheter-based approaches, surgical therapy, and placement of an intravenous filter also play a role.¹⁻³

■ EPIDEMIOLOGY

VTE commonly complicates the course of hospitalized patients,⁴⁻⁶ especially those in the ICU⁷⁻⁸ and sometimes despite VTE prophylaxis.⁹ Acute PE remains an underdiagnosed condition, despite advances in diagnosis. In a study of trauma patients in an ICU, CT scans detected incidental PE in 24% of cases.⁷ A study of mechanically ventilated patients, undergoing chest CT unrelated to suspected PE, found PE in 18.7% of examined individuals.⁸

Studies of patients who received DVT prophylaxis in medical ICUs suggest that the existence of PE is detected in less than 2.5% of these populations.¹⁰⁻¹² Of note, a small proportion of patients will enter the ICU with undiagnosed proximal DVT.¹⁰ Studies of ICU patients who received DVT prophylaxis and underwent lower extremity venous compression ultrasound screening once to twice a week, and additional testing when clinically indicated, have a DVT incidence rate of 5.4% to 23.6%.^{9,10,13} In autopsy studies of critically ill patients, PE was found in 7% to 27%, and clinicians did not suspect PE in about one-third of these patients.¹⁴⁻¹⁸

PE causes approximately 100,000 to 180,000 deaths per year in the United States, and it ranks high among the causes of cardiovascular mortality.^{19,20} Most patients who die from PE remain undiagnosed during life,²¹ and many succumb suddenly or within a few hours of the acute event before therapy is initiated or takes effect.²² The mortality and morbidity of acute PE vary by clinical presentation, the presence of comorbid disease, and other underlying factors. Despite modern methods for diagnosis and treatment, PE continues to have a high mortality rate.²³⁻²⁵ During the first week after the diagnosis of PE, death and major bleeding occur more frequently than recurrent VTE.²³ Most deaths due to PE within the first 3 months of follow-up occur during the first week after diagnosis.²³ For example, in the Prospective Investigation of Pulmonary Embolism Diagnosis (PIOPED), 10.5% of patients died during follow-up after diagnosis; 9 out of 10 (90%; 95%, 55.5%-99.7%) patients who died due to PE, died within 2 weeks of diagnosis.²⁶ In the Management and Prognosis in Pulmonary Embolism Trial (MAPPET), 9.6% of patients who had acute PE died during the hospital stay, and the majority (94.2%) of deaths were due to PE.²⁷ Overall, the majority of treated patients with PE survive and do not have a recurrent event or a major complication associated with therapy, although patients in the ICU typically have a more complicated course than others.^{12,28}

■ RISK FACTORS FOR PE

A method of classifying PE risk factors uses the categories of inherited, acquired, or unknown (idiopathic) (Box 71-1). Patients at risk for PE often have a combination of patient-related and setting-related

risk factors. Some risk factors are temporary or reversible, and others are permanent.^{29,30} The most common inherited risk factor for VTE includes gene polymorphisms (e.g., factor V Leiden and prothrombin gene G20210A), and less common abnormalities that lead to deficiencies of the natural anticoagulants protein C, protein S, and antithrombin.³¹⁻³³ The majority of patients with VTE do not require testing for such abnormalities, and most testing is not relevant in an ICU setting. Unprovoked (i.e., spontaneous or idiopathic) thrombosis, despite the absence of an inherited or acquired thrombophilia, predisposes patients to future thrombosis more than a history of provoked thrombosis due to a transient risk factor.²⁹ Acquired hypercoagulable states may arise secondary to malignancy, immobilization, infection, trauma, surgery, collagen vascular diseases, nephrotic syndrome, heparin-induced thrombocytopenia (HIT), disseminated intravascular coagulation (DIC), medications (e.g., estrogen), and pregnancy. Central intravenous catheters significantly increase the risk for DVT,³⁴⁻⁴¹ and femoral catheters especially increase the risk of DVT and associated PE.^{8,36,38} Hospitalized patients often have multiple risk factors for VTE, and most patients in the ICU have strong risk factors.^{8,13,29,34,42,43} The risk of VTE increases as the number of risk factors rises.^{32,44}

■ NATURAL HISTORY

Patients who do not receive treatment for acute PE may have a short-term mortality rate as high as 30%,⁴⁵ although a much lower rate is present in ambulatory patients.⁴⁶ Unselected patients with PE or VTE have a 30-day all-cause mortality rate of about 10%, based on registries and hospital discharge datasets.⁴⁷⁻⁵⁰ PE recurrence or progression may cause about half of the early deaths after the initial PE.⁵¹ While treated PE in normotensive patients who do not have evidence of right ventricular (RV) dysfunction has a short-term mortality rate of approximately 2%, the mortality rate increases as high as 30% in patients with shock and up to 65% in patients who present with cardiac arrest.^{4,12,50,52-55}

Patients have a reasonably low rate of VTE recurrence after treatment, especially while still in the ICU. Although the rate of recurrence is highest during the first few weeks after diagnosis, only about 2% of patients have recurrent VTE during that period.⁵⁶⁻⁵⁸ Patients with unprovoked VTE tend to have more recurrences than those who have an event provoked by a temporary risk factor.²⁹ In patients with acute PE and a subsequent recurrent VTE, the recurrent event typically occurs as PE instead of DVT.⁵⁹

Following an acute PE, about one-third of patients do not have complete resolution of thrombus within the first follow-up year, as determined by lung perfusion scintigraphy.⁶⁰⁻⁶² A small but significant proportion of patients with PE develop chronic thromboembolic pulmonary hypertension.⁶³

■ RISK FACTORS FOR DEATH AFTER PE

Older studies have associated hemodynamic decompensation after acute PE with an approximate three- to sevenfold increase in mortality.⁶⁴⁻⁶⁵ More recent large observational studies of PE have also described systolic arterial hypotension as the most significant prognostic indicator of poor outcome.^{23,27,50}

BOX 71-1**Common Risk Factors for PE in the ICU****CLINICAL RISK FACTORS**

Surgical and nonsurgical trauma, spinal cord injury
 Recent surgery
 Malignancy (risk varies based on malignancy)
 Nephrotic syndrome
 Heart failure
 Stroke; lower extremity paralysis
 Previous venous thromboembolism
 Age (>40 years, and increased risk with increased age)
 Obesity
 Pregnancy/postpartum
 Medications (e.g., estrogens, specific chemotherapeutic agents, erythropoietin-stimulating agents)
 Immobilization

ICU-ACQUIRED RISK FACTORS

Sepsis
 Central venous catheter
 Pharmacologic paralysis
 Respiratory failure
 Acute heart failure
 Mechanical ventilation
 Acute renal failure; dialysis
 Blood products (e.g., platelets, recombinant factor VIIa)
 Vasopressors

INHERITED OR ACQUIRED ABNORMALITIES

Factor V Leiden
 Prothrombin 20210A
 Protein C deficiency
 Protein S deficiency
 Antithrombin deficiency
 Antiphospholipid antibody syndrome
 Heparin-induced thrombocytopenia
 Myeloproliferative syndromes
 Dysfibrinogenemia

PATHOPHYSIOLOGY

An overall balance between thrombogenic stimuli and protective mechanisms is present under baseline physiologic conditions and prevents clinically meaningful thrombosis. The body's fibrinolytic system and natural anticoagulants typically prevent hypercoagulable states.⁶⁶ Categories of factors that predispose the development of venous thrombi include the activation of blood coagulation, vascular damage, and venous stasis (Virchow's triad). The protective mechanisms that counteract these thrombogenic stimuli include (1) the inactivation of activated coagulation factors by circulating inhibitors (e.g., antithrombin and activated protein C); (2) the clearance of activated coagulation factors and soluble fibrin/polymer complexes by the reticuloendothelial system and liver; and (3) dissolution of fibrin by fibrinolytic enzymes derived from plasma and endothelial cells and the digestion of fibrin by leukocytes. Impairment or deficiency within these systems may result in a hypercoagulable state and the formation of venous thrombi. The interaction between coagulation enzymes and cellular activity leads to thrombin generation and clot formation. Venous thrombi, composed predominantly of fibrin and red cells, have a variable and smaller component of platelets and leukocytes.⁶⁷

Thrombi may form in the veins, superficially (superficial vein thrombosis, SFVT) or deep (deep vein thrombosis, DVT). DVT may embolize to the lungs and lodge in the pulmonary arteries (i.e., PE). PE originates from thrombi in the deep veins of the lower extremities in at least 90% of patients.^{16,68,69} Most clinically important PE arise from thrombi in the popliteal or more proximal deep veins of the lower extremities, and usually, only part of the thrombus embolizes.⁷⁰ About half (i.e., 30% to 70%) of patients with PE detected by angiography also

have asymptomatic DVT of the lower extremities identified by a compression ultrasound.^{16,68,71-73} Asymptomatic PE occurs in at least 50% of patients with objectively documented symptomatic proximal lower extremity DVT.^{5,16} Other less common sources of PE include the deep pelvic veins, renal veins, inferior vena cava, right atrium and ventricle, and axillary veins. Air, fat, tumor, and foreign bodies may also embolize to the lungs.

Although many patients have asymptomatic PE, the acute clinical importance of PE depends on the embolic clot burden, the patient's cardiorespiratory reserve, and neurohumoral responses. PE may cause significant pulmonary and cardiovascular sequelae (Fig. 71-1).^{74,75} Pulmonary vascular obstruction may lead to increased pulmonary vascular resistance, and the elevation of the pulmonary artery pressure requires an occlusion of about 30%-50% of the total cross-sectional area of the pulmonary arterial bed.⁷⁶ Hypoxic vasoconstriction can also increase pulmonary vascular resistance. Shock commonly develops when PE occurs in the main pulmonary arteries or bifurcations. Inflammatory mediators (e.g., thromboxane A₂ and serotonin) play a role in vasoconstriction of the pulmonary vasculature, decreased perfusion, and increased vascular resistance.⁷⁷ Pulmonary arterial obstruction and vasoconstriction may produce hypoxemia via impaired alveolar gas exchange and increased lung dead space ventilation.⁷⁸ Ventilation-perfusion mismatch caused by capillary bed overflow in nonobstructed vessel zones will also contribute to hypoxemia. If present, a right to left shunt (e.g., patent foramen ovale) can also contribute to hypoxemia and might also predispose the patient to a paradoxical embolism. Hemodynamic disturbances also contribute to respiratory failure, as in the situation where low cardiac output results in the desaturation of mixed venous blood.

Patients typically compensate for PE-associated increased lung dead space ventilation⁷⁸ with increased ventilatory drive and minute ventilation, which leads to hypocapnia.^{74,75} However, patients with underlying lung disease or those receiving mechanical ventilation (i.e., sedated and not breathing above the set ventilator respiratory rate) may develop hypercapnia.⁷⁵ Normally, the end-tidal CO₂ approximates the PaCO₂. However, since end-tidal gas consists of a mixture of non-dead space and dead space gas, and since CO₂ does not transfer from the blood to the airway in nonperfused areas, the end-tidal CO₂ decreases in association with the increased dead space.⁷⁵

Abrupt increases in pulmonary vascular resistance associated with PE result in right ventricle (RV) dilation. Neurohumoral activation and subsequent inotropic and chronotropic stimulation improves flow through the partially obstructed pulmonary vascular bed.⁷⁸ However, prolonged elevations of RV pressure may cause a leftward bowing of the interventricular septum and decreased left ventricular (LV) filling during diastole.⁷⁹ If present, a right bundle branch blockage may contribute to the desynchronization of the ventricles. Decreased LV filling during early diastole can lead to decreased cardiac output and systemic hypotension.⁸⁰ Myocardial inflammation, increased right ventricular wall stress, and increased oxygen demand may cause RV ischemia and result in decreased RV contractility, RV cardiac output, LV preload, LV cardiac output, and systemic blood pressure.

RV microinfarction leads to the elevation of serum troponin levels.^{74,81-86} Cardiac myocyte injury triggers the release of the cardiac-specific markers cardiac troponin T (cTnT) and cardiac troponin I (cTnI). However, elevated cTnI levels may not occur with RV dysfunction. Cardiac wall stress associated with high ventricular filling pressures and myocardial hypoxia trigger the release of *B-type natriuretic peptides* (e.g., brain natriuretic peptide, BNP) and the N-terminal fragment of its prohormone, N-terminal pro-BNP (NT-proBNP), from coronary arteries and cardiac ventricular cells.^{74,81,87,88}

RISK FACTORS FOR RECURRENT VTE

Various studies have attempted to identify risk factors for recurrent VTE, including recurrent PEs that cause death in patients presenting initially with PE. Factors contributing to recurrent VTE in anticoagulated patients include the length of initial hospitalization, presence of

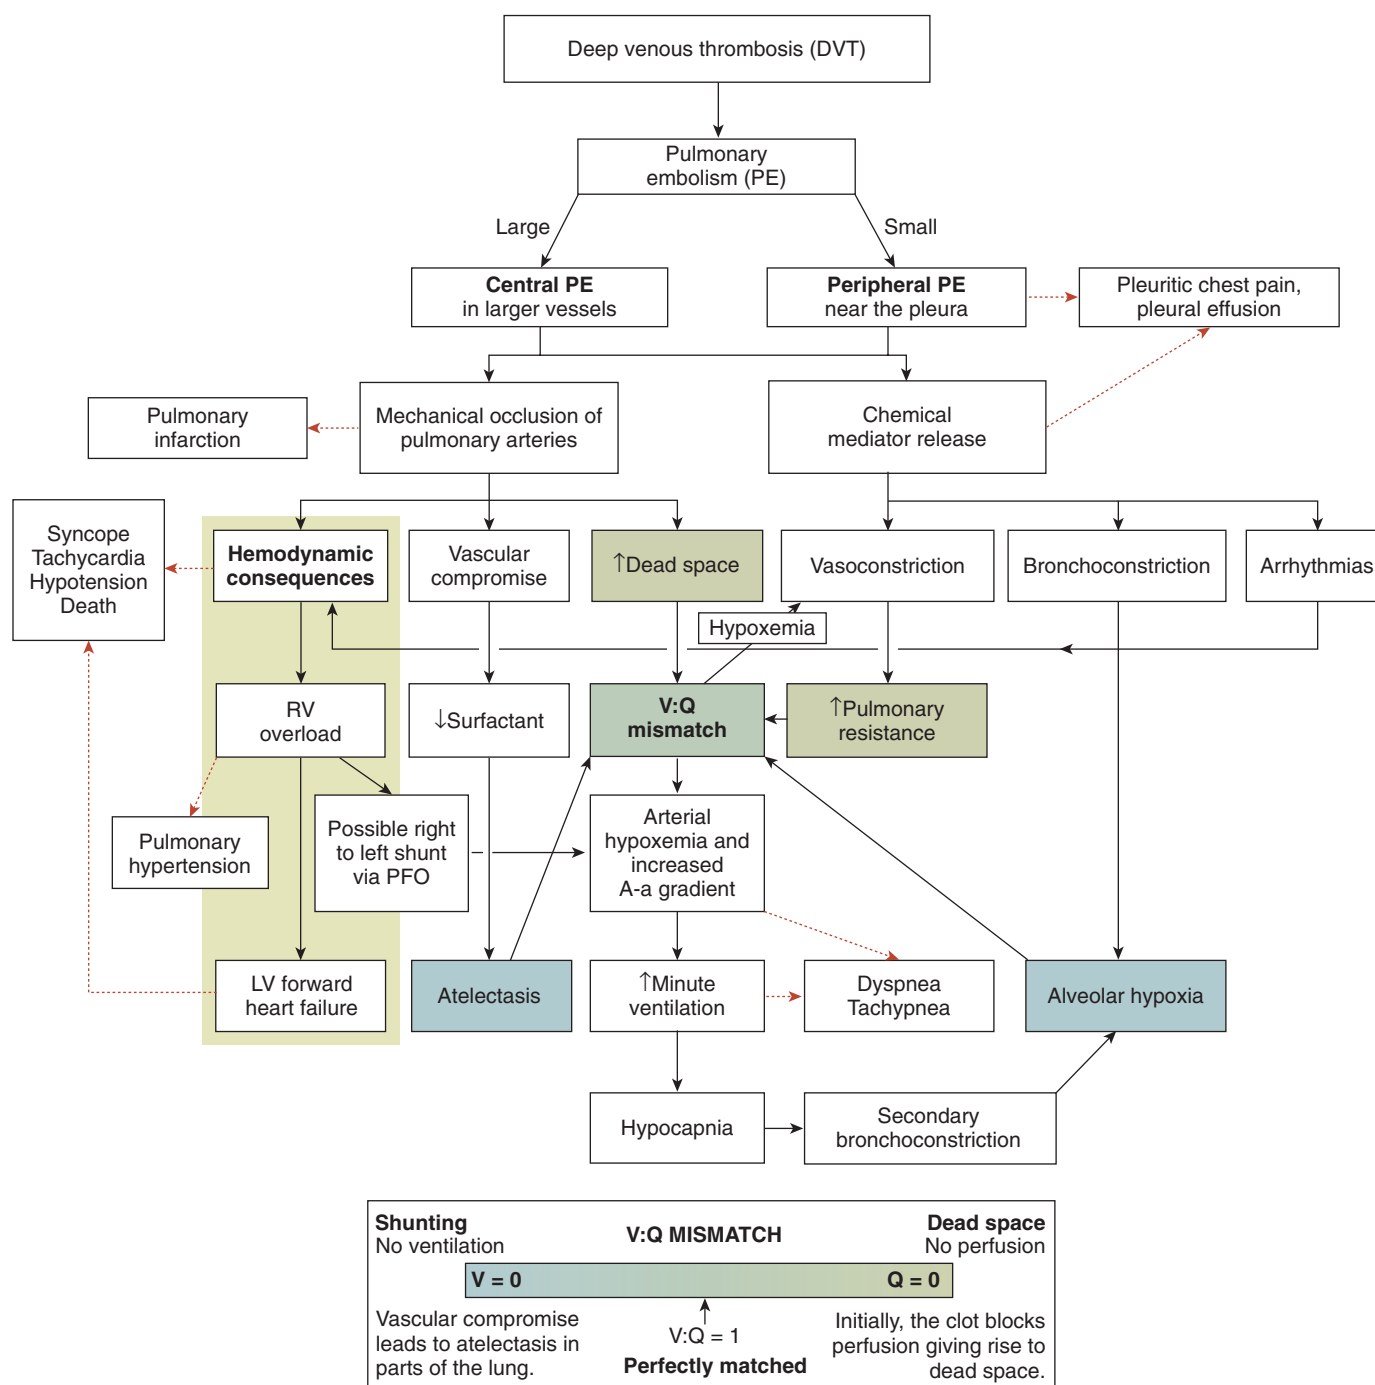

FIGURE 71-1 ■ PE pathophysiology. A-a, alveolar-arterial; DVT, deep vein thrombosis; PE, pulmonary embolism; PFO, patent foramen ovale; RV, right ventricle; VQ, ventilation-perfusion. (Adapted from Wong E, Chaudry S: Venous thromboembolism. McMaster Pathophysiology Review (www.pathophys.org), Hamilton, Ontario, Canada.)

cancer, older age, hospitalization for multiple injuries, and surgery within 3 months.^{89,90}

The location of DVT has an impact on the incidence of recurrence, and the presence of an iliofemoral DVT is associated with a higher rate of recurrent VTE compared with popliteal vein thrombosis.⁹¹ Additionally, the extensiveness of the DVT (e.g., venographic Marder Score) has a positive association with recurrent VTE events.⁹²

■ DIAGNOSIS (Fig. 71-2)

Clinical Features

The clinical presentation of PE depends on the size, number, and distribution of the emboli and on the patient's underlying cardiorespiratory reserve. Many cases of PE that occur in ICU patients go

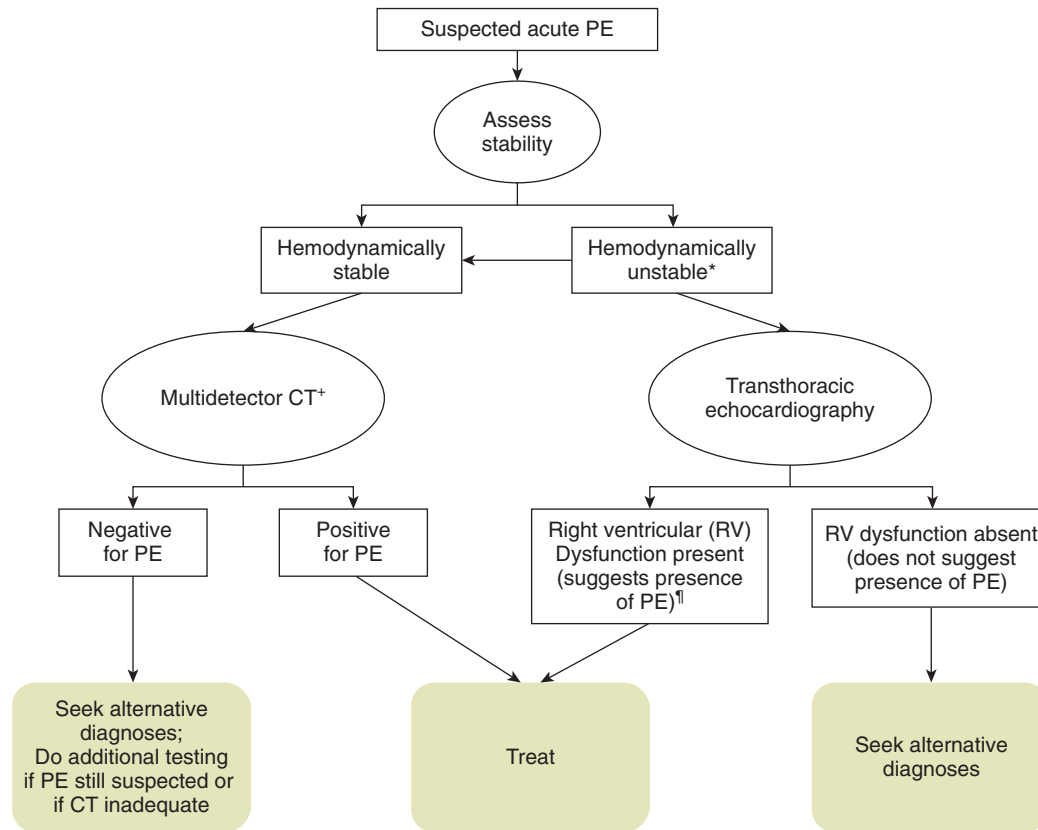

FIGURE 71-2 ■ Diagnostic evaluation for suspected acute pulmonary embolism (PE) in the intensive care unit (ICU). CT, computed tomography; ICU, intensive care unit; PE, pulmonary embolism. *Search for alternative and concomitant diagnoses. [†]If contraindication to intravenous (IV) contrast exists, consider ventilation-perfusion scintigraphy, lower extremity venous compression ultrasound, or MR angiography. [‡]Try to confirm the presence of PE with additional testing. Proximal lower extremity DVT serves as a surrogate to PE in the appropriate clinical setting.

unrecognized.^{93,94} Symptoms and signs of PE often overlap with other conditions in the ICU, and without objective testing, they alone should not be used to diagnose PE. The clinical manifestations of acute PE can generally be divided into several syndromes that overlap considerably: (1) dyspnea, sometimes with marked hypoxemia and tachypnea, with limited other associated clinical manifestations; (2) pulmonary infarction, often associated with pleuritic chest pain, cough, hemoptysis, pleural effusion, and pulmonary infiltrates on the chest radiograph or CT; (3) right ventricular failure or cardiovascular collapse, associated with tachycardia, hypotension, and possibly syncope; and (4) other nonspecific clinical features including fever, wheezing, anxiety, hypoxemia, and unexplained arrhythmia.^{95,96}

Differential Diagnosis

The differential diagnosis in patients with suspected PE includes cardiopulmonary disorders for each of the modes of presentation (see [Clinical Features](#)). For the presentation of dyspnea, tachypnea, and hypoxemia, the possible diagnoses include atelectasis, pneumonia, pneumothorax, pleural effusion, aspiration, pulmonary edema, bronchial obstruction, alveolar hemorrhage, and other pulmonary disorders. For pulmonary infarction exhibited by pleuritic chest pain or hemoptysis, possible diagnoses include pneumonia, pneumothorax, pericarditis, aortic dissection, pulmonary or bronchial neoplasm, pleurisy, costochondritis, muscle strain, and rib fracture. For the clinical presentation of right-sided heart failure or cardiovascular collapse, possible diagnoses include myocardial infarction, acute massive hem-

orrhage, sepsis, cardiac tamponade, heart failure, hypovolemia, and tension pneumothorax. Other considerations related to PE include sepsis, foreign body, fat, air, amniotic fluid, tumor emboli, and in situ thrombosis (e.g., sickle cell chest syndrome).¹ Though these conditions and venous thromboembolic PE may have similar supportive treatment, the requirement for unique disease-specific treatments requires a correct diagnosis.

Diagnostic Testing

DVT and PE are not separate and unrelated disorders but rather represent a continuous syndrome of VTE in which the initial clinical presentation may be symptoms of DVT, PE, or both. Therefore, strategies for the diagnosis of VTE include testing for PE and DVT.^{16,68,69} In the ICU, patients should undergo a rapid assessment for the potentially life-threatening disorders on the differential diagnosis list.

Assessment of Clinical Probability

Pretest probability plays a key role in the workup of patients with suspected PE, though most clinical prediction rules (e.g., Wells,⁹⁷ simplified Wells,⁹⁸ Geneva,⁹⁹ and simplified Geneva scores^{100,101}) have mainly undergone validation outside of the ICU setting.^{26,97,100-113} Combining pretest probability (e.g., Wells score) with diagnostic tests improves their diagnostic accuracy.¹¹⁴ Typical ICU evaluation for patients with suspected PE, including chest radiograph, electrocardiogram, and arterial blood gas, can assist in determining pretest probability and clinical severity, as well as information about other disorders,

even though they provide nonspecific information for PE diagnosis. If PE remains on the differential diagnosis list, then it warrants more specific testing.

Oxygen Assessment

Patients with PE most often do not have hypoxemia (i.e., low PaO₂ or SpO₂), though most have an abnormal alveolar-oxygen gradient.⁹⁶ Some studies suggest that up to 40% of patients with acute PE have a normal arterial oxygen saturation (SaO₂), and 20% have a normal alveolar-oxygen gradient.^{115,116}

Electrocardiography

Sinus tachycardia occurs in most patients with PE.⁹⁶ Classic findings on EKG of S1Q3T3 (S in V1, Q wave in V3, and T wave inversion in V3) and right bundle branch block do not occur in most patients with PE, and they have low positive predictive value when they do occur.¹¹⁷ Signs of RV strain that include right axis deviation and right ventricle hypertrophy may suggest the presence of PE.¹¹⁷⁻¹¹⁹

D-Dimer Assay

Plasma D-dimer levels become elevated in association with the activation of coagulation and fibrinolysis. Although D-dimer testing assists with directing a VTE workup in patients who have a low clinical probability of PE, it does not have a significant utility in the ICU. This is because most patients suspected of PE in the ICU have a high pretest probability of PE or a high likelihood of having a false-positive (i.e., low positive predictive value) D-dimer test.^{94,120} Therefore, patients in the ICU suspected of having VTE should undergo objective diagnostic imaging testing for PE without or despite any D-dimer test results.^{121,122}

Diagnostic Imaging for Suspected PE

In the ICU, the stability of the patient, the ability to lie flat and hold the breath, the findings on other imaging studies, the ability to receive an intravenous dye load, appropriate intravenous line access, and test availability play an important role in deciding which diagnostic test(s) to perform (see Fig. 71-2).

Chest Radiograph. The chest radiograph (CXR) usually reveals nonspecific findings in association with acute PE, but it may help to assess for other diagnoses promptly. Classic PE findings such as Westermark sign and Hampton's hump do not commonly occur.¹²³

Contrast-Enhanced Chest Computed Tomography (PE Protocol CT). Contrast-enhanced (multidetector) helical chest computed tomography (CT), also known as *CT angiography* (CTA), has become the most common and important diagnostic modality for assessing patients with suspected PE.¹²⁴⁻¹²⁷ CTA requires adequate IV access, ability to safely receive an intravenous iodinated dye load, ability to lie down and hold one's breath, ability to be safely transported to the imaging facility, appropriate body size/habitus to fit in the scanner, and willingness to receive radiation. Patients with a contraindication to CTA or inadequate CTA results should undergo other forms of testing.

The advantages of CTA over ventilation-perfusion scintigraphy (V/Q scan) include more diagnostic results (positive or negative) with fewer indeterminate or inadequate studies, and the detection of alternative or concomitant diagnoses (e.g., dissecting aortic aneurysm, pneumonia, and malignancy). CT may also assess for right ventricular dysfunction.^{128,129}

The PIOPED II study assessed the accuracy of multidetector CTA and combined CTA-CT venography (CTV).¹¹⁴ Among 824 patients with a reference diagnosis (based on a diagnostic algorithm) and a completed CT study (mainly 4-detector), CTA had poor image quality and inconclusive results in 6%. CTA had a sensitivity of 83% and a specificity of 96%. Positive results on CTA in combination with a high or intermediate probability of PE by Wells' criteria¹³⁰ had a positive predictive value (PPV) of 92% to 96%, while normal findings via CTA with a low clinical probability had a negative predictive value (NPV) of 96%. Thus, concordance of PE suspicion and CT results does not require further diagnostic testing. CT had poor diagnostic accuracy (about 60% PPV and NPV) when the clinical probability and the CT

results showed discordance, suggesting that PE suspicion/CT discordance should lead to further testing.¹¹⁴

The clinical significance of isolated subsegmental PE on CTA has raised debate, especially since it has a low PPV and poor interobserver reliability.^{131,132} In the presence of this type of PE, a venous compression ultrasound may assist with diagnostic and treatment decisions.^{1,2,133}

Incidental PE, clinically unsuspected but found on a CT, occurs in a small percentage of patients. Recommendations have recently moved for the treatment of small incidental PE (e.g., subsegmental or smaller),² although the guidelines recommend the treatment of larger (more proximal) incidental PE.^{1,2}

Radionuclide Lung Scanning. Despite the advances in chest CT diagnostic testing, lung ventilation/perfusion (V/Q) scintigraphy continues to play a role in the diagnosis of suspected PE.²⁶ VQ scans use an intravenous injection of technetium (Tc)-99m-labeled macroaggregated albumin particles to block a small fraction of the pulmonary capillaries and inhaled tracers (e.g., xenon-133 gas, Tc-99m-labeled aerosols, or Tc-99m-labeled carbon microparticles [Technegas]). VQ scans base their diagnosis on the expectation that hypoperfused segments of the lung (e.g., from PE) should exhibit normal ventilation and result in a V/Q mismatch as detected by gamma camera images.^{134,135}

V/Q scanning has an important role in patients with absolute or relative contraindications to CTA (e.g., IV contrast allergy, pregnancy, renal failure) or indeterminate CTA results.¹³⁶ For patients unable to be transported for a CT, they may undergo portable perfusion (Q) scanning (and possibly ventilation [V] scanning, if not mechanically ventilated) in the ICU. Additionally, since V/Q scans have significantly lower radiation exposure to the breast than CTA,¹³⁷ some consider it as the first-line imaging test for women of reproductive age.¹²⁵

V/Q scan results, earlier classified as normal, very low probability, low probability, intermediate probability, or high probability of PE,²⁶ are now more commonly classified as normal (and near normal), low probability, nondiagnostic (intermediate probability), and high probability.^{138,139} Some studies and guidelines propose a three-tier classification of normal (rules out PE), nondiagnostic (neither diagnostic for PE nor rules it out with a high likelihood), and high probability (diagnostic for PE in most patients).^{1,126,140,141} Similar to CT scan testing, VQ scan testing for PE has improved test characteristics when its results are combined with the objective grading of clinical suspicion. A normal or low-probability VQ scan in the setting of a low clinical suspicion adequately rules out PE, and a high-probability VQ scan in the setting of a high clinical suspicion adequately confirms PE with an acceptably small number of misclassified cases. However, these two scenarios of concordant test results and clinical suspicion only account for the minority of test results in hospitalized patients.^{26,142,143} In addition, V/Q scanning remains most useful in patients with a normal chest radiograph. Unfortunately, nondiagnostic V/Q scans commonly occur in the setting of an abnormal chest radiograph,²⁶ a common occurrence in the ICU. Approximately 70% of V/Q scans have inconclusive or nondiagnostic results, even when considered together with the pretest clinical probability.^{26,68,143} Nondiagnostic/indeterminate V/Q scan results or discordance between the clinical suspicion and the test results should lead to further testing because of concerns regarding diagnostic misclassification (false positives and negatives).¹ In this setting, objective testing for DVT with a venous compression ultrasound may provide added diagnostic value, and the ease of performance at the bedside often makes this test a good next step in the ICU.

Pulmonary Angiography. Pulmonary angiography uses intravenous iodinated contrast and selective catheterization of the pulmonary arteries. Diagnostic criteria for PE on angiography include two projections (views) of direct evidence of a thrombus seen as a filling defect or an amputation (cut-off) of a pulmonary arterial branch.²⁶ The procedure has a similar diagnostic accuracy to CT scanning.¹⁴⁴ Similar to CT, reader reliability significantly drops at the subsegmental level.^{145,146} Pulmonary angiography has a diagnostic role for the evaluation of suspected acute PE in the narrow setting of nondiagnostic noninvasive testing, high clinical suspicion, and available expertise. Pulmonary

angiography also plays a role in the percutaneous, catheter-directed treatment of acute PE. For patients who do undergo pulmonary angiography, hemodynamic measurements obtained during right heart catheterization may prove useful for management. Pulmonary angiography has a relatively low risk in patients who do not have pulmonary hypertension or cardiac failure.^{26,142} Pulmonary angiography has similar limitations and contraindications to CT scanning for ICU patients.

Cardiac Testing

Echocardiography. Echocardiography may detect a right heart thrombus¹⁴⁷⁻¹⁵⁰ or be used to visualize an embolism in transit. Findings on an echocardiogram that indirectly suggest the presence of PE include RV dilation and hypokinesis, an increase in the RV/LV diameter ratio; tricuspid regurgitation, paradoxical septal motion, interventricular septal shift toward the LV, McConnell's sign (i.e., hypokinesis of the free wall of the RV with normal motion of the apex), decreased tricuspid annulus plane systolic excursion (TAPSE),¹⁵¹ and pulmonary artery dilation. If echocardiography identifies pulmonary artery pressures or RV wall thickness beyond values consistent with acute RV pressure overload, this suggests an underlying or previously present RV dysfunction and the presence of some associated causal disorder. For hemodynamically stable patients with suspected acute PE, an abnormal echocardiogram with any of the findings noted above does not rule in PE (low PPV) unless a thrombus is seen.¹⁵²⁻¹⁵⁵ Echocardiography has a low NPV, so a lack of findings does not exclude PE in hemodynamically stable patients.¹⁵⁶⁻¹⁵⁸ Echocardiogram is not recommended as a routine part of a suspected PE evaluation in hemodynamically stable and normotensive patients.¹

In hypotensive patients, an echocardiogram that does not show signs of right heart dysfunction almost certainly excludes PE as the cause of the hemodynamic decompensation. An echocardiogram does assist with evaluating alternative etiologies for the hypotension (e.g., pericardial tamponade, valvular heart disease, left ventricular dysfunction, aortic dissection, and hypovolemia).

For patients diagnosed with PE by other means, echocardiography may assess cardiopulmonary reserves and evidence of end-organ damage (i.e., RV dysfunction). Echocardiography also provides a number of independent parameters related to pulmonary hemodynamics and can identify patients who have PE and a significantly increased risk of death.^{85,151,159-163} An echocardiogram may also provide clues to the cause of a cardiac arrest. Thus, echocardiography may assist with identification of potential candidates for thrombolysis or catheter fragmentation.¹⁶⁴⁻¹⁶⁷

Transesophageal ECHO (TEE) is not typically part of the diagnostic evaluation of patients with suspected or confirmed PE. However, TEE may identify central thrombus, especially in hemodynamically unstable patients.^{168,169}

Cardiac Blood Biomarkers. Cardiac biomarkers (e.g., troponin and BNP) have a low diagnostic accuracy for PE. These markers may have prognostic value (e.g., elevated values predict decompensation or death),^{83-85,163,170} although the literature lacks management studies that have validated their use in making treatment decisions in patients with acute PE. The NPV of these markers may be most useful for prognosis; those without elevated troponin and BNP have a lower risk of mortality from acute PE.¹

Venous Compression Ultrasonography. Venous compression ultrasonography uses the validated criterion of incomplete compressibility of a deep vein (assumed due to thrombus) for the diagnosis of DVT.^{72,171} A recent study of a lower extremity venous compression ultrasound performed by intensivists in the ICU had a sensitivity of 85% and a specificity of 96% for detecting DVT.¹⁷²

Most PE originates from lower extremity DVT.⁶⁸ Lower extremity venous compression ultrasonography shows DVT in 30%-50% of patients with acute PE.⁷⁰⁻⁷³ In studies of patients with suspected PE who had a positive D-dimer, the complete lower extremity venous ultrasound had a diagnostic yield almost twice that of testing limited to the proximal lower extremity, though distal DVT occurred without PE in about one-third of patients.^{173,174} However, the presence of

proximal lower extremity DVT has a high PPV for PE.¹⁰⁰ A venous compression ultrasound negative for DVT does not exclude the presence of PE.⁶⁸

Venous compression ultrasonography has a diagnostic role in patients with suspected PE, particularly those with inconclusive CT results,²⁶ nondiagnostic lung scan results,¹⁴³ or the inability to undergo imaging for PE, since detection of DVT (especially proximal DVT) confirms the presence of VTE. Detection of proximal DVT by objective testing provides an indication for standard treatment regardless of the presence or absence of PE, and it reduces the need for further diagnostic testing. For patients who have nondiagnostic CT or lung scan or CT results combined with negative lower extremity venous compression ultrasound results and adequate cardiopulmonary reserve, serial venous compression ultrasound testing and the withholding of anticoagulant therapy can be used as alternatives to pulmonary angiography.^{125,175,176}

DVT may occur in non-lower extremity sites in patients in the ICU.^{177,178} Patients with central venous access, especially those with cancer, have an increased risk of upper extremity DVT.^{177,179} Upper extremity DVT may cause PE. A recent large nested prospective cohort study did not find an association between clinically apparent non-lower extremity DVT and ICU mortality, although the study did not have adequate power for this assessment.¹⁷⁷ Upper extremity venous compression ultrasound has a lower sensitivity compared to lower extremity testing because of the higher difficulty for imaging the proximal veins.¹⁷¹

Integrated Strategies for Diagnosis of Pulmonary Embolism

Figures 71-2 and 71-3 summarize the approach to the diagnosis of suspected PE in the ICU. The specific approach used should depend on individual patient circumstances that dictate the urgency of the testing and treatment, what testing can be performed when the testing can occur, and what tests have already been completed. The approach should also rely on the local availability of technology, the expertise with the different diagnostic techniques, the timing of the tests, and the diagnostic test characteristics.

The diagnostic testing approach for patients in the ICU suspected of having PE depends on the presence or absence of shock and clinical instability. Without these conditions, patients may undergo transport for testing outside of the ICU. For unstable patients or those at high risk of complications during transport, patients should probably undergo bedside testing. Unstable patients should also undergo rapid testing to work through the differential diagnosis list of life-threatening illnesses and to allow for rapid intervention.

CLASSIFICATION

The PE classification schema uses the terms *acute* versus *chronic*, and acute PE has the most relevance to the ICU. Acute PE classification systems have often used the terms *massive*, *submassive*, and *other* over the past 50 years, and these categories relate to cardiovascular effects of the PE and patient prognosis.^{29,180} Massive PE has often been defined by acute right heart failure and associated hypotension (e.g., systolic blood pressure <90 mm Hg or a drop >40 mm Hg from baseline for at least 15 minutes) that remains present despite volume resuscitation and vasopressor therapy. Clinicians should treat related factors, such as arrhythmias and decreased cardiac output, and unrelated factors, such as hypovolemia, before defining the hypotension as refractory. Submassive PE has described patients who have PE-associated hemodynamic stability in the setting of right ventricular (RV) dysfunction. Patients who do not have symptoms and signs of massive or submassive PE have been grouped into the "other" category. Clinical characteristics define PE severity classification, although radiologic grading may also use these terms based on clot burden or the degree of arterial obstruction.

The recent European Society of Cardiology guidelines has moved away from the massive/submassive/other PE classification system

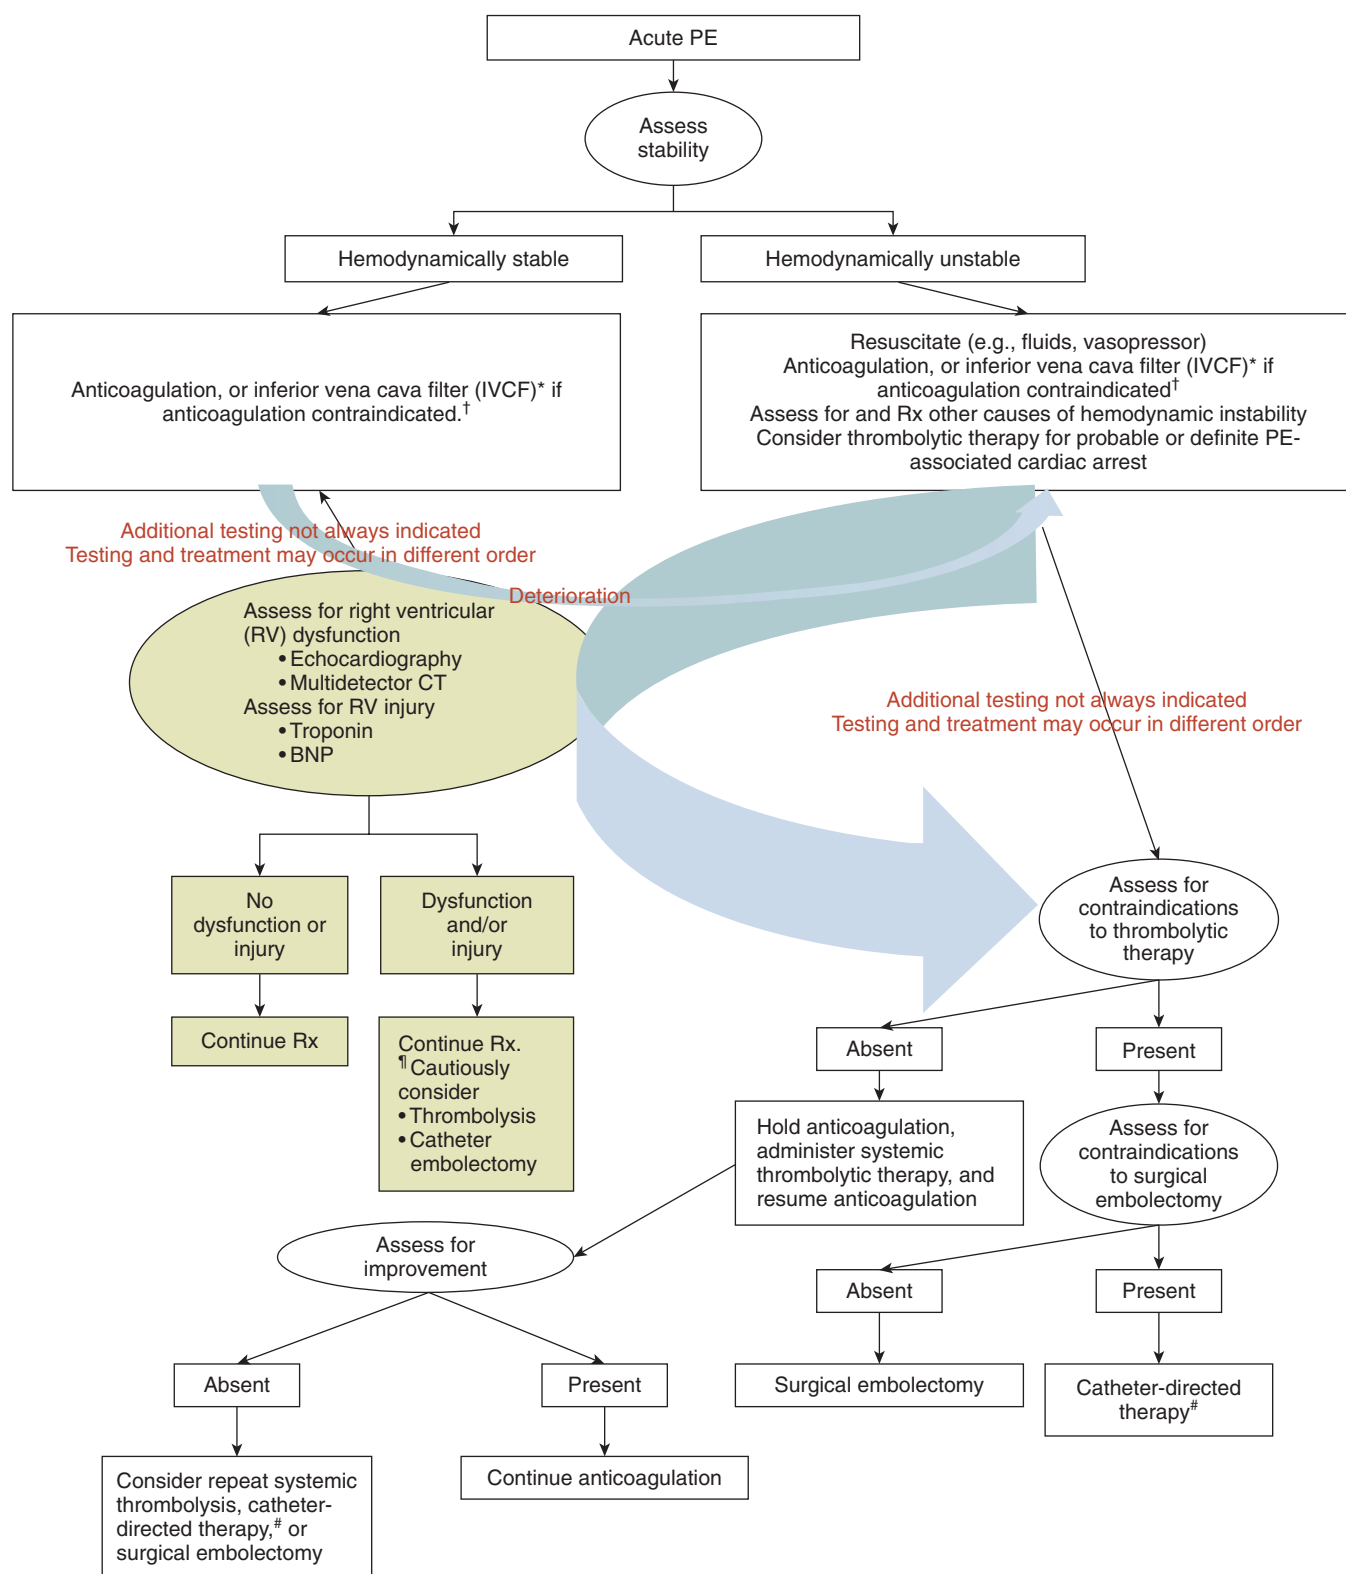

FIGURE 71-3 ■ Treatment of confirmed acute PE in the ICU. BNP, brain natriuretic peptide; CT, computed tomography; CUS, compression ultrasound; ICU, intensive care unit; IVCF, inferior vena cava filter; PE, pulmonary embolism; RV, right ventricle; Rx, treatment. *Temporary or permanent IVCF. †Anticoagulate after IVCF placement once contraindication to anticoagulation resolves. ‡If contraindications do not exist. †Catheter-directed therapy may include mechanical clot treatment and thrombolysis; the decision to use depends on availability and local expertise.

TABLE 71-1 Mortality Risk Classification of Patients Who Have Acute PE

| EARLY MORTALITY RISK | | RISK PARAMETERS AND SCORES | | | |
|----------------------|-------------------|----------------------------|--------------------------------------|--|--|
| | | SHOCK OR HYPOTENSION | PESI CLASS III-V OR sPESI $\geq 1^a$ | SIGNS OF RV DYSFUNCTION ON AN IMAGING TEST ^b | CARDIAC LABORATORY BIOMARKERS ^c |
| High | | + | (+) ^d | + | (+) ^d |
| Intermediate | Intermediate-high | — | + | Both positive | |
| | Intermediate-low | — | + | Either one (or none) positive ^e | |
| Low | | — | — | Assessment optional; if assessed, both negative ^e | |

LV, left ventricular; PE, pulmonary embolism; PESI, pulmonary embolism severity index; RV, right ventricular; sPESI, simplified pulmonary embolism severity index.

^aPESI Class III to V indicates moderate to very high 30-day mortality risk; sPESI ≥ 1 point(s) indicates high 30-day mortality risk.

^bEchocardiographic criteria of RV dysfunction include RV dilation and/or an increased end-diastolic RV-LV diameter ratio (in most studies, the reported threshold value was 0.9 or 1.0), hypokinesia of the free RV wall, or increased velocity of the tricuspid regurgitation jet. Computed tomographic (CT) angiography (four-chamber views of the heart) criterion for RV dysfunction consists of an increased end-diastolic RV/LV diameter ratio (≥ 0.9 or 1.0).

^cMarkers of myocardial injury (e.g., elevated cardiac troponin-I or -T concentrations in plasma) or heart failure as a result of right ventricular dysfunction (elevated natriuretic peptide concentrations in plasma).

^dClassify shock or hypotension as high risk, despite any PESI or sPESI score.

^eClassify low-risk PESI (class I-II) or sPESI patients (score of 0) who have associated elevated cardiac biomarkers or signs of RV dysfunction on imaging tests into the intermediate to low-risk category. Adapted from Konstantinides SV, Torbicki A, Agnelli G, Danchin N, Fitzmaurice D, Galiè N, Gibbs JS, Huisman MV, Humbert M, Kucher N, Lang I, Lankeit M, Lekakis J, Maack C, Mayer E, Meneveau N, Perrier A, Pruszczyk P, Rasmussen LH, Schindler TH, Svitil P, Vonk Noordegraaf A, Zamorano JL, Zompatori M; Authors/Task Force Members. 2014 ESC Guidelines on the diagnosis and management of acute pulmonary embolism: The Task Force for the Diagnosis and Management of Acute Pulmonary Embolism of the European Society of Cardiology (ESC) Endorsed by the European Respiratory Society (ERS). Eur Heart J 2014;35:3033-3073 (Table 9).

toward an early mortality risk-based classification system that drives treatment decisions (Table 71-1).¹ The guideline uses four key risk assessment categories that assess for (1) hemodynamic instability (i.e., shock or hypotension present), (2) imaging-detected (echocardiogram or CT) signs of RV dysfunction, (3) elevated clinical risk score (by Pulmonary Embolism Severity Index [PESI] or simplified PESI, Table 71-2), and (4) abnormal cardiac laboratory biomarkers (i.e., troponin, BNP). High-risk PE patients have hemodynamic instability with imaging-detected signs of RV dysfunction, with or without an elevated clinical risk score and with or without abnormal cardiac laboratory biomarkers. Intermediate-risk PE patients do not have hemodynamic instability, but they have an elevated clinical risk score, and they may or may not have imaging-detected signs of RV dysfunction and or abnormal cardiac laboratory biomarkers. Low-risk PE patients do not have abnormalities in any of the four key risk assessments. The PE severity classification systems do not address all important clinical events such as hypoxemia, respiratory failure requiring mechanical ventilation, or worsening cardiovascular status that might occur within a specific risk class (e.g., greater tachycardia or a drop in blood pressure not meeting criteria for hypotension).

PROGNOSTIC ASSESSMENT AND SEVERITY INDICES

Indicators of a poor prognosis or adverse outcomes for patients who have PE include hemodynamic instability/hypotension, signs of RV dysfunction, elevated troponin, elevated BNP, coexisting DVT, thrombus burden, and right ventricular thrombus.^{23,25,70,81-85,92,151,157,159-161,163,170,181-189} Underlying risk factors include an age greater than 70 years, congestive heart failure, chronic obstructive pulmonary disease (COPD), and cancer.¹⁹⁰⁻¹⁹² Several prognostic scoring systems (e.g., the Pulmonary Embolism Severity Index [PESI],^{190,191} and the simplified PESI [sPESI],¹⁹² Geneva risk score,⁹⁹ simplified Geneva risk score,¹⁹³ Hestia criteria,¹⁹⁴ Shock Index,¹⁹⁵ Global Registry of Acute Coronary Events [GRACE] score,¹⁹⁶ PREP score,⁶² PROTECT multimarker index,¹⁸⁷ Bova score,¹⁸⁸ and RIETE score exist.¹⁹⁷ However, the clinical prediction tools have not been specifically developed for patients in the ICU. Of note, the prognostic markers often predict varying degrees of risk in different types of patients, such as those with hypotension and those without the condition.

TABLE 71-2

Original and Simplified Pulmonary Embolism Severity Index (PESI)

| VARIABLE | ORIGINAL PESI | SIMPLIFIED PESI |
|---|---------------|-------------------------------------|
| Age | Age, in years | 1 (if age > 80 years) |
| Male sex | +10 | — |
| History of cancer | +30 | 1 |
| History of heart failure | +10 | 1 for either or both of these items |
| History of chronic lung disease | +10 | — |
| Pulse > 110 beats/min | +20 | 1 |
| Systolic blood pressure < 100 mm Hg | +30 | 1 |
| Respiratory rate > 30 breaths/min | +20 | — |
| Temperature < 36°C | +20 | — |
| Altered mental status | +60 | — |
| Arterial oxyhemoglobin saturation (SaO ₂) < 90% | +20 | 1 |

30-DAY MORTALITY RISK STRATA (BASED ON THE SUM OF POINTS)

Assessment of RV Dysfunction

Studies have identified echocardiographic findings indicative of RV dysfunction as independent predictors of an adverse outcome in patients who have acute symptomatic PE.^{151,157,181,183,198} A meta-analysis found that RV dysfunction on the echocardiography had an odds ratio (OR) for short-term mortality of 2.5 (95% CI, 1.2 to 5.5).¹⁹⁹ Studies have also validated the use of CT angiography for assessing RV dilation.^{200,201} A recent systematic review showed that CT-assessed RV dysfunction had an association with increased risk of mortality in normotensive patients with PE (OR 1.8; 95% CI, 1.3 to 2.6), but the relatively small likelihood ratios and the small increase in the ability to classify risk with this approach suggest that the usefulness of basing therapeutic decision making solely on CT results does not appear warranted.¹⁸⁶ However, echocardiographic RV dysfunction has a weak independent association with short-term PE-related complications. Taken together, these findings suggest that RV dysfunction (assessed either by echocardiography or CT angiography) in itself should not significantly drive the decision to give thrombolytic therapy in normotensive patients with acute PE.²

Single markers of right ventricular (RV) dysfunction (e.g., on echocardiography, on spiral computed tomography [CT], elevated BNP) or myocardial injury (e.g., elevated cardiac troponin T or I testing) have an insufficient positive predictive value for PE-specific complications to drive decision making toward recanalization procedures, and studies have suggested that they only identify an intermediate- to low-risk group of patients with PE.^{25,85,186}

Assessment of Myocardial Injury

Studies of patients with acute PE have demonstrated an association between myocardial injury (assessed by elevated serum levels of troponin or heart-type fatty acid-binding protein [HFABP]) and short-term adverse in-hospital outcomes.^{83,86,202} Measurement of troponin and brain or B-type natriuretic peptides (BNP) may assist with estimating disease severity and prognosis in patients presenting with PE.^{85,159–163} A meta-analysis of studies of normotensive patients with acute PE showed a significant association between elevated troponin levels and increased mortality (OR 4.3; 95% CI, 2.1 to 8.5).⁸⁵ However, troponin alone did not appear to change the pretest clinical significance to a posttest probability of death. Moreover, the usefulness of basing therapeutic decision making solely on troponin levels does not appear to be warranted. While some observational studies have suggested that cardiac biomarkers may possess a prognostic value additive to that of echocardiography,^{81,82,182} the findings from the recently published Pulmonary Embolism Thrombolysis Trial (PEITHO) suggest that such a combination might not be strong enough to identify patients reliably at an increased risk for PE-related complications.²⁰³

Thrombus Burden

In patients who have VTE, thrombus burden has an association with death.^{70,92,204} In a prospective single-center cohort study of outpatients diagnosed with a first episode of acute symptomatic PE, investigators assessed the prognostic significance of concomitant DVT during the 3-month follow-up period after PE diagnosis.¹⁹² The DVT assessment by CCUS had a positive predictive value for a 90-day PE-related mortality of 6.6% (95% CI, 4.1% to 9.2%).

D-Dimer

Studies have correlated D-dimer levels with proximal location of PE, serious comorbidity, and mortality in patients with acute symptomatic PE.^{193,205–209} Recently, investigators used the international prospective Registro Informatizado de la Enfermedad TromboEmbolica Venosa (RIETE Registry) to assess the prognostic value of D-dimer levels obtained near the time of acute PE diagnosis for outcomes over the ensuing 15-days after diagnosis.²¹⁰ In a cohort of 1707 patients, the

all-cause mortality, increased as the D-dimer level increased, from 2.7% in the first quartile to 7.0% in the fourth quartile. Patients with D-dimer levels in the highest quartile also had an increased risk of fatal PE (OR 2.0; 95% CI, 1.0 to 3.8) and major bleeding (OR 3.2; 95% CI, 1.5 to 7.0). PE (either initial or recurrent) caused 45% of the deaths during the 15-day follow-up.

Combination of Prognostic Tests

Although they raised concern about PE severity, single markers of RV dysfunction and myocardial injury have an insufficient positive predictive value for PE-specific complications to drive decision making toward aggressive (e.g., thrombolytic) therapy.¹⁸² Observational studies have suggested an incremental prognostic value of the association of markers of RV dysfunction and injury over either alone^{81,82} or the combination of imaging testing and biomarkers to clinical prediction rules.¹⁸⁵

The PREP score includes the variables of cardiogenic shock, BNP, RV to left ventricle (LV) diameter ratio, underlying cardiac or respiratory disease, altered mental status, and cancer.⁶² The derivation study classified 247 of 570 PE patients (43%) in the highest risk category, and they had a risk of PE-related serious adverse events at 30 days of 22.9%.⁶²

The PROTECT study^{183,187} derived (n = 848) and validated (n = 529) a multimarker prognostication tool that consisted of BNP, cTnI, Simplified Pulmonary Embolism Severity Index [sPESI], and CCUS imaging (for concomitant DVT) for normotensive patients diagnosed with acute symptomatic PE in an emergency department (available at www.PEprognosis.com). The combination of abnormal test results for all PROTECT prognostic tests had a positive predictive value for the prediction of a complicated course (defined as death from any cause, hemodynamic collapse, and/or adjudicated recurrent PE) of 25.8% in the derivation cohort and 21.2% in the validation cohort.

A patient-level meta-analysis involving 2874 normotensive patients presenting to the hospital with acute PE found that significant predictors of PE-related complications included tachycardia, mild hypotension, cardiac dysfunction, and myocardial injury.¹⁸⁸ The Bova et al. model [Bova risk score] identified three stages (I, II, and III) with 30-day PE-related complication rates of 4.2%, 10.8%, and 29.2%, respectively. A recent study validated the Bova score for accurately assessing the risk for PE-related complications that occur within 30 days of PE diagnosis.¹⁸⁹

Observational studies have suggested that the combination of clinical variables (i.e., tachycardia and mild hypotension), myocardial injury, and RV dysfunction, particularly in those with concomitant DVT, identifies the more severe intermediate-risk patients with acute PE (i.e., “intermediate-high risk” according to European Society of Cardiology guideline)¹ who might benefit from intensive monitoring and even recanalization procedures. However, prognostic tools cannot predict a risk that is high enough to justify primary reperfusion in hemodynamically stable patients.^{2,211}

TREATMENT OF PE (see Fig. 71-3)

Objectives and Principles of Treatment

The objectives of PE treatment in ICU patients include (1) supportive care (e.g., treatment of hypotension and respiratory failure), (2) prevention of clinical deterioration or death associated with PE, (3) facilitating the resolution of PE, (4) prevention of recurrent VTE, and (5) avoidance of complications from therapy. Clinicians should make their treatment decisions for PE based on confidence in the diagnosis of PE, hemodynamic status of the patient, the degree of RV dysfunction/injury, bleeding risk, prognosis, patient preferences, and patient-specific factors that could affect treatment safety and efficacy.

In general, patients that have a nonhigh bleeding risk should undergo prompt initiation of empiric anticoagulation upon a high clinical suspicion of PE before the completion of diagnostic tests if the

testing cannot be completed rapidly. Patients diagnosed with PE should then rapidly achieve therapeutic anticoagulant levels. Anticoagulant therapy should undergo appropriate monitoring. Patients who have PE ruled out should have anticoagulation discontinued and prophylaxis for venous thromboembolism initiated.

Resuscitation

Regarding patients not already in an ICU, patients who have high-risk PE should be transferred to an ICU. Select patients who have intermediate-risk PE (submassive PE) could benefit from monitoring for deterioration in the ICU.

Patients who have PE and present with shock have a high risk of deterioration and death, especially in the hours following the development of shock. Hemodynamic instability associated with PE should lead to prompt resuscitation and consideration for thrombolytic therapy.

Volume Administration

Judicious volume infusion for resuscitation of RV dysfunction and decreased RV preload associated with PE may improve cardiac output.²¹² However, overdistention of the RV with volume resuscitation may impair subsequent left ventricular (LV) filling, LV output, and coronary perfusion.²¹³ Thus, patients who have hypotension associated with PE should receive appropriate amounts of intravenous fluids.²⁸

Vasopressors

Limited data exist regarding the use of vasopressors in humans with acute PE. A canine model demonstrated the superiority of norepinephrine over phenylephrine in increasing cardiac output and RV coronary blood flow, although both agents similarly improved the mean arterial blood pressure.²¹⁴ Although epinephrine and dobutamine may provide inotropic support, dobutamine has the disadvantage of causing or worsening systemic hypotension. Interestingly, raising the cardiac index may cause or worsen ventilation-perfusion mismatch through the redistribution of blood flow from partially obstructed pulmonary arteries to unobstructed vessels.²¹⁵ Thus patients who have hypotension associated with PE should undergo cautiously monitored vasoactive support.

Vasodilator Therapies

Interest has arisen in the use of pulmonary arterial vasodilators (e.g., inhaled nitric oxide and oral phosphodiesterase inhibitors) for the treatment of acute PE.^{216,217} Vasodilator drugs can affect hypoxic vasoconstriction, platelet activation, and the release of vasoactive mediators (e.g., endothelin, thromboxane). Theoretically, vasodilator treatment would lower the pulmonary artery pressure and unload the RV. However, clinical trials have not confirmed their efficacy and safety. Thus, the literature does not support the routine use of pulmonary arterial vasodilators in patients who have hypotension or marked hypoxemia associated with PE.

Supplemental Oxygen

Patients with PE often have an elevated alveolar-arterial gradient. In the patients who have PE associated with hypoxemia,^{74,75,96} supplemental oxygen will usually allow for the achievement of normoxemia.

Mechanical Ventilation and Sedation

Intubation and mechanical ventilation may assist with the treatment of rare episodes of respiratory failure associated with PE or may occur as part of resuscitation associated with PE (e.g., cardiac arrest). Some patients already receiving mechanical ventilation develop PE. For patients who have PE and undergo mechanical ventilation, ventilator-associated positive pressure ventilation may decrease the RV preload. In addition, sedative use associated with mechanical ventilation may cause systemic hypotension. Various approaches to mechanical ventilation (e.g., prone ventilation) can also decrease RV afterload.²¹⁸ Avoidance of excessive tidal volume and positive end-expiratory pressure, as

well as careful sedation management, should help to prevent the development or worsening of hypotension.²¹⁹

Mechanical Circulatory Support

Patients who have PE and associated circulatory collapse could potentially benefit from mechanical circulatory support.^{220,221} However, studies have not thoroughly investigated such therapies in this setting.

Initial Anticoagulation Considerations

Anticoagulation, the mainstay of treatment for acute PE, prevents new clot formation, extension and embolism of the source of the PE (e.g., DVT), and the recurrence of PE. Before making anticoagulant choices, clinicians should consider anticoagulant drug efficacy and safety regarding anticoagulant bioavailability and absorption issues, onset and time to peak, half-life, mechanism of clearance, drug interactions, ability to monitor anticoagulant effect, and reversibility. Clinicians should also consider issues related to upcoming or potential procedures or surgeries. Anticoagulant therapy for ICU patients typically should focus on short-term issues while long-term treatment plans can be determined after patients leave the ICU. Patients with PE and hypotension who receive anticoagulation should receive unfractionated heparin (UFH) instead of low-molecular-weight heparin (LMWH) or fondaparinux since the latter agents have not undergone rigorous testing under such conditions. In addition, for those patients who will or might receive thrombolytic therapy, the use of an anticoagulant with a short-half life might provide the greatest safety. Although ICU-specific studies of anticoagulant therapy for PE would provide the most relevant data, most treatment recommendations about standard anticoagulant treatment in the ICU are extrapolated from non-ICU data.

Bleeding Risk Assessment

All patients should undergo a bleeding risk assessment and evaluation for contraindications to anticoagulant therapy before the initiation of such treatment.² Absolute contraindications to anticoagulant treatment include intracranial bleeding, severe active bleeding, malignant hypertension, or recent brain, eye, or spinal cord surgery. Relative contraindications include recent major surgery, recent cerebrovascular accident, nonsevere active bleeding, severe hypertension, severe renal or hepatic failure, and severe thrombocytopenia (e.g., platelets <50,000/ μ L).²⁹ Since aspirin and other nonsteroidal antiinflammatory drugs significantly increase the risk of bleeding for patients who receive anticoagulants,²²² their use should be avoided or minimized. While studies have identified risk factors for anticoagulant-associated bleeding in patients who have VTE,^{223,224} those with a high bleeding risk often receive anticoagulation therapy because the benefits typically outweigh the risks.

Initial Anticoagulation

As described above, clinicians should consider using empiric initial parenteral anticoagulant therapy for suspected PE, especially for patients who do not have a high bleeding risk and for scenarios that include delayed diagnostic testing. After the confirmation of PE diagnosis, ICU patients deemed appropriate for anticoagulation should usually receive a parenteral agent.

Heparin Therapy

Unfractionated Heparin Therapy. Despite the frequent use of LMWH and newer nonvitamin K antagonist target-specific oral anticoagulants, unfractionated heparin (UFH) still has a major role in the initial treatment of VTE in ICU patients. Pertinent to patients in the ICU, UFH has the advantage of a relatively short half-life, a lack of significant dependence on renal clearance, and the reversibility of the anticoagulant effect of protamine sulfate.²²⁵

The anticoagulant activity of UFH depends on a unique pentasaccharide, present on about a third of heparin molecules, that binds to antithrombin (AT) and potentiates the inhibition of thrombin and

activated factor X (FXa).²²⁵⁻²²⁷ To a lesser degree, in a process independent of AT, heparin also catalyzes the inactivation of thrombin via plasma cofactor II.²²⁵ Heparin has a number of effects that include the release of tissue factor pathway inhibitor (TFPI), suppression of platelet function, increase in vascular permeability, and the binding to numerous plasma and platelet proteins, endothelial cells, and leukocytes.²²⁶

The anticoagulant response to a standard dose of UFH varies widely among patients. This varied response makes it necessary to monitor the anticoagulant effects of UFH, using either the activated partial thromboplastin time (aPTT) or heparin levels, and to titrate the dose to the individual patient.²²⁵

The efficacy of UFH therapy depends partly upon achieving a critical therapeutic level of UFH within the first 24 hours of treatment.²²⁸⁻²³⁰ Clinical trials have shown that failure to achieve a therapeutic aPTT threshold by 24 hours had a 23% subsequent recurrence VTE rate over 3 months of follow-up, compared with a rate of 4% to 6% for the patient group who had therapeutic levels at 24 hours.^{229,230} The minimum therapeutic threshold of UFH, as measured by the aPTT, is 1.5 times the mean of the control value or the upper limit of the normal aPTT range.²²⁸⁻²³⁰ The therapeutic range for UFH corresponds to a UFH blood level of 0.2 to 0.4 U/mL by the protamine sulfate titration assay and 0.35 to 0.70 by the anti-FXa assay. Each laboratory should establish the minimal therapeutic level of UFH, as measured by the aPTT, that will provide a UFH blood level of at least 0.35 U/mL by the anti-FXa assay for each batch of thromboplastin reagent being used, particularly if a new batch of reagent is provided by a different manufacturer.²²⁵

Numerous studies of UFH therapy have demonstrated the difficulties of successfully administering IV UFH. The previously popular clinical practice of using an ad hoc approach to UFH dose titration frequently resulted in inadequate therapy. Multiple studies have supported the use of a prescriptive approach or protocol for administering IV UFH for the treatment of patients with VTE.^{228,230} The protocols achieve therapeutic UFH levels in the vast majority of patients. A weight-based nomogram results in fewer episodes of recurrent VTE as compared to standard care.^{230,231} A commonly used nomogram uses an IV UFH bolus of 80 U/kg and an initial continuous IV drip rate of 18 U/kg/hour.²³⁰ The nomogram then determines the UFH adjustments based on the aPTT. Nomograms typically recommend checking the first aPTT about 6 hours after initiating UFH therapy. However, for ICU patients that have high-risk PE, and for some patients who have intermediate-risk PE, an aPTT obtained about 90 minutes after the UFH bolus should have a very high value (e.g., >150 sec). If the aPTT does not reach such a high value in this setting, then another UFH bolus is indicated.

The adjusted-dose and unadjusted dose of subcutaneous (SC) UFH has demonstrated efficacy in the initial treatment of VTE.²³²⁻²³⁵ Similar to IV UFH, achieving the therapeutic range by 24 hours improves the efficacy of SC UFH.²³⁶ However, because of concerns about absorption associated with body edema and hypotension, the IV route is preferred over the SC route in the ICU.²³⁷

Low-Molecular-Weight Heparin. Chemical or enzymatic depolymerization of UFH produces LMWHs that have different chemical structures and pharmacokinetics.^{238,239} Few studies have compared different LMWHs with respect to clinical outcomes, so the impact of these differences remains unclear.²³⁹ In comparison to UFH, LMWHs have increased bioavailability (>90% after subcutaneous injection), longer half-life, and more predictable clearance. These characteristics of LMWHs enable a weight-based once- or twice-daily subcutaneous injection that does not require laboratory monitoring.^{225,238-240} However, the renal clearance of LMWHs requires a dose or frequency reduction or complete avoidance (e.g., renal failure) in patients with significantly reduced renal function.

LMWHs have fewer serious complications, such as bleeding²³¹ and heparin-induced thrombocytopenia,²⁴¹⁻²⁴³ when compared with UFH. However, the subcutaneous use of anticoagulants in the ICU may lack efficacy. Among ICU patients receiving LMWH DVT prophylaxis,

those receiving vasopressors had lower anti-FXa activity than those not receiving vasopressors.^{244,245} Studies have shown variable results regarding anti-FXa activity in the setting of LMWH use in the setting of subcutaneous edema.^{237,246} The appropriate dosing of LMWH in morbidly obese patients remains unclear.²⁴⁷ Thus, in comparison to UFH, LMWH's lack of complete reversibility, its longer half-life, its renal clearance, and possible reduced efficacy in hypotensive and edematous patients may lead to the preferred use of UFH in the ICU.

Fondaparinux. Fondaparinux, a synthetic indirect inhibitor of factor Xa, has efficacy and safety similar to UFH²⁴⁸ for the initial treatment of PE or LMWH for the initial treatment of DVT.²⁴⁹ Fondaparinux has ICU issues similar to LMWHs, which may lead to the preferred use of UFH in this setting.

Oral Agents

Vitamin K Antagonists. Until recently, typical patients with PE might receive initial therapy of IV UFH, LMWH, or fondaparinux, overlapped with an oral vitamin K antagonist (VKA). However, those patients ill enough to receive ICU care often have reasons to forgo concomitant and long-term VKA therapy. The possibility of undergoing invasive procedures or surgery, high bleeding risk, the potential use of fibrinolytics, and other issues often weigh against the use of anticoagulants that have a long half-life (e.g., VKA). Long-term anticoagulation plans are best dealt with after the clinical problems requiring ICU care have been fully addressed.

Nonvitamin K Antagonist Target-Specific Oral Anticoagulants. Non-VKA oral anticoagulants have been classified into two target-specific categories, direct thrombin inhibitor (e.g., dabigatran) and direct Xa inhibitors (e.g., rivaroxaban, apixaban, and edoxaban). Since dabigatran²⁵⁰ and edoxaban²⁵¹ require 5 to 10 days of overlapping parenteral anticoagulant therapy for the treatment of VTE, these agents would not typically be used as initial therapy in the ICU. Compared to warfarin, the non-VKA oral agents have a more rapid onset, shorter half-life, wider therapeutic window, and more predictable pharmacokinetics. In general, these features allow the use of rivaroxaban²⁵² and apixaban²⁵³ for sole VTE oral therapy without the need for an overlapping parenteral agent, titration or dose adjustments in patients with normal renal function, and routine monitoring. Issues of concern that should limit the use of the non-VKA oral anticoagulants in the ICU include the need for oral intake and gastrointestinal absorption, the relatively long half-life in comparison to UFH, the lack of approved antidotes for the factor Xa inhibitors, drug level effects based on renal function, drug interactions, and the inability to monitor the anticoagulant effect fully.

Thrombolytic Therapy

Unlike the anticoagulants described above, thrombolytics lead to rapid clot lysis by converting plasminogen to plasmin. Fibrinolytic treatments now primarily consist of more fibrin-specific drugs (activators of plasmin where fibrin is already bound, such as in blood clots) that include alteplase, reteplase, and tenecteplase. Earlier fibrinolytic drugs consisted of less fibrin-specific agents (i.e., activators of plasmin in all body fluids) that included streptokinase and urokinase.²⁹ A number of tissues, including endothelial cells, produce the naturally occurring enzyme (serine protease) alteplase (recombinant tissue-type plasminogen activator, tPA; Activase). Alteplase has fibrin specificity, and fibrin-bound tPA has increased affinity for plasminogen; non-fibrin-bound tPA in the systemic circulation does not extensively activate plasminogen. The standard alteplase dose for PE is 100 mg IV over 2 hours. Recombinant technology has produced the tPA, reteplase (recombinant plasminogen activator, rPA; Retavase). Compared to alteplase, reteplase has less fibrin specificity and a longer half-life. For PE, reteplase is typically given as 10 U IV over 2 minutes, and 30 minutes later, another 10 U is given IV over 2 minutes. Genetic engineering has produced the multiple point mutant of recombinant tPA, tenecteplase (TNK-tPA; TNKase). Tenecteplase's longer plasma

half-life than reteplase and alteplase allows for its single intravenous bolus injection (e.g., 50 mg IV over 5 seconds). In comparison to the other fibrinolytic agents, it has high fibrin specificity and resistance to inhibition by plasminogen activator inhibitor 1 (PAI-1). Alteplase, streptokinase, and urokinase have U.S. Food and Drug Administration (FDA) approval for the treatment of PE, and most guidelines recommend the use of alteplase.

Thrombolytic therapy provides more rapid lysis of PE and more rapid restoration of pulmonary perfusion than anticoagulant treatment, with associated reduction in pulmonary artery pressure and resistance and an improvement in right ventricular function.^{28,52,167,254,255} Despite the belief that these drugs have life-saving effects, thrombolytic agents have not convincingly shown a mortality benefit in clinical trials.²¹¹ Although a recent meta-analysis suggested that thrombolytic therapy offers a survival benefit to patients with acute PE (OR 0.53), fibrinolytics also carry a significant risk of bleeding.²⁵⁶ Thrombolytic therapy has had mixed efficacy in normotensive patients who have acute PE associated with signs of right heart dysfunction (submassive PE or intermediate to high-risk PE) while being associated with an increase in major hemorrhage that includes intracranial bleeding.^{1,2,167,203,254-266} In addition, few head-to-head comparisons of thrombolytic drugs for acute PE have been conducted.²⁶⁷ Taking data from all published clinical trials and other studies into account,^{132,256,263,265,266,268} the guidelines recommended the use of thrombolytic therapy mainly in patients with acute PE and associated hemodynamic instability (i.e., high-risk or massive PE).^{1,2} Rescue thrombolytic therapy may benefit patients who develop cardiovascular collapse after the initial treatment with anticoagulant therapy alone.²

Fibrinolytic therapy appears to have the most benefit when initiated within 48 hours of PE symptom onset. However, thrombolysis may still have efficacy when used in patients who have had symptoms for up to 2 weeks.²⁶⁹

The primary risk of thrombolytic therapy is major bleeding, which may include intracranial hemorrhage, and bleeding associated with treatment with fibrinolytic agents may lead to death. A registry study showed a 22% risk of major bleeding and a 3% risk of intracranial bleeding in thrombolysis recipients who had acute massive (high-risk) PE.⁵² A recent meta-analysis suggests that fibrinolytics have a significant risk of major hemorrhage (9.2%) and intracranial hemorrhage (1.5%).²⁵⁶ In patients deemed appropriate for thrombolytic therapy, a higher adult age, and comorbidities are associated with an increased risk of bleeding.²⁷⁰ Before using thrombolytic therapy, it is crucial to ensure that no contraindications to its use exist (Box 71-2).

UFH may be discontinued or continued during thrombolytic therapy.¹ Guidelines typically recommend the discontinuation of treatment with any of the other anticoagulants,² although a recent study of tenecteplase did not stop the required LMWH therapy around the single dose lytic/placebo treatment.²⁶¹ If UFH is not continued during lytic therapy, it is reasonable to restart it when the aPTT drops back into the therapeutic range (from a supratherapeutic value). UFH should be continued after the completion of lytic therapy until it is deemed safe to use agents that have longer half-lives and decreased reversibility.

Imminent or Actual Cardiac Arrest

Placebo-controlled pilot studies have shown a higher rate of return of spontaneous circulation and perhaps survival after a bolus of either 50 mg of recombinant tissue plasminogen activator (rTPA; alteplase)²⁷¹ or 50 mg of tenecteplase.²⁷²

Complications of Anticoagulation and Thrombolytic Therapy

The most frequent severe adverse effects of anticoagulant and thrombolytic therapies consist of bleeding. UFH and LMWH also have the infrequent but concerning risk of heparin-induced thrombocytopenia.²⁷³⁻²⁷⁶

BOX 71-2 Contraindications* to Fibrinolytic Therapy

ABSOLUTE CONTRAINDICATIONS

Prior intracranial hemorrhage
Known structural cerebral vascular lesion
Known malignant intracranial neoplasm
Ischemic stroke within past 3 months (excluding stroke within past 3 hours)
Suspected aortic dissection
Serious active bleeding or major bleeding diathesis (excluding menses)
Significant closed-head trauma or facial trauma within past 3 months

RELATIVE CONTRAINDICATIONS

History of chronic, severe, poorly controlled hypertension
Severely uncontrolled hypertension on presentation (SBP > 180 mm Hg or DBP > 110 mm Hg)
History of ischemic stroke more than 3 months ago
Traumatic or prolonged (>10 minutes) CPR, or major surgery within past 3 weeks
Internal bleeding within past 4 weeks
Noncompressible vascular punctures
Recent invasive procedure
Prior exposure (more than 5 days ago) or prior allergic reaction to streptokinase
Pregnancy
Active peptic ulcer
Pericarditis or pericardial fluid
Current use of anticoagulant (e.g., warfarin sodium) with INR > 1.7 or PT > 15 seconds
Age > 75 years
Diabetic retinopathy

SBP, systolic blood pressure; DBP, diastolic blood pressure; CPR, cardiopulmonary resuscitation; INR, international normalized ratio; PT, prothrombin time.

*Severity of condition and judgment of clinician will determine the categorization of absolute versus relative contraindication; list not all inclusive.

Bleeding

Patients at particular risk of bleeding are those who have had recent surgery or trauma or who have other clinical factors that predispose individuals to bleeding on anticoagulants (Box 71-3).²⁹ Procedures, surgeries, and medications that affect the coagulation system or platelet function may also increase the risk of bleeding.

Management of bleeding will depend on the cause, location, and severity of bleeding, as well as concomitant factors that include medications, laboratory values, and patient preferences. Clinically relevant bleeding should lead to discontinuation of UFH or thrombolytic therapy temporarily or permanently, and supportive measures should be provided. If urgent reversal of heparin effect is required, protamine sulfate can be administered.²²⁵

Heparin-Induced Thrombocytopenia

Heparin-induced thrombocytopenia (HIT), a well-recognized complication of UFH and LMWH therapy, usually occurs within 5 to 10 days after heparin treatment has started.²⁷³⁻²⁷⁶ Approximately 1% to 2% of patients receiving UFH will experience a decrease in platelet count to less than the normal range or a 50% fall in the platelet count within the normal range.²⁷³⁻²⁷⁶ In the majority of cases, this direct effect of heparin on platelets causes mild to moderate thrombocytopenia and has no adverse consequences. However, patients receiving UFH may develop an immune thrombocytopenia mediated by immunoglobulin G (IgG) antibodies directed against a complex of PF4 and heparin.²⁷³⁻²⁷⁶

LMWH has a lower incidence of HIT in comparison to UFH^{241,242,273-279}; however, the clinical manifestations of HIT associated with LMWH use may be as or more severe than those observed with UFH. Furthermore, UFH and LMWH have different kinetics for the nadir of platelet count, onset, and duration of thrombocytopenia.²⁴¹

HIT may have a rapid onset in patients who have had recent exposure to heparin.²⁷³⁻²⁷⁶ The onset of HIT may be delayed and occur

BOX 71-3

Risk Factors for Bleeding* with Initial Anticoagulant Therapy**RISK FACTORS**

| | |
|-------------------|---|
| Age > 65 years | Diabetes |
| Age > 75 years | Anemia |
| Previous bleeding | Antiplatelet therapy |
| Cancer | Poor anticoagulant control |
| Metastatic cancer | Comorbidity and reduced functional capacity |
| Renal failure | Recent surgery |
| Liver failure | Frequent falls |
| Thrombocytopenia | Alcohol abuse |
| Previous stroke | |

*List not all inclusive.

The increased bleeding risk associated with a risk factor will vary with (1) severity of the risk factor (e.g., location and extent of metastatic disease, platelet count), (2) temporal relationships (e.g., interval from surgery or a previous bleeding episode), and (3) previous effectiveness of correction of cause of bleeding (e.g., upper-GI bleeding).

Compared with low-risk patients (0 risk factors), moderate-risk patients (1 risk factor) have a twofold risk, and high-risk patients (≥ 2 risk factors) have an eightfold risk of major bleeding. Adapted from the American College of Chest Physicians, Kearon C, Akl EA, Comerota AJ, et al. Antithrombotic therapy for VTE disease: Antithrombotic Therapy and Prevention of Thrombosis, 9th ed: American College of Chest Physicians Evidence-Based Clinical Practice Guidelines. Chest. 2012 Feb;141(2 Suppl.):e432 (Table 2).

as long as several weeks after the end of exposure to heparin, thus making this syndrome more difficult to diagnose. Furthermore, the incidence and severity of HIT vary among different patient populations. Patients having cardiac or orthopedic procedures have a higher incidence of HIT than medical patients.²⁷³⁻²⁷⁶

The development of HIT has an association with arterial and venous thromboses known as heparin-induced thrombocytopenia and thrombosis (HITT). These thrombotic events may lead to serious complications that include compartment syndrome, limb ischemia (requiring subsequent amputation), and death.²⁷³⁻²⁷⁶

Most centers use HIT-antibody testing with enzyme-linked immunosorbent assay (ELISA) for the PF4-heparin complex to diagnose HIT. Since the risk of false-positive tests with this very sensitive test, a potential diagnosis of HIT should undergo confirmation with a highly specific functional assay, such as a serotonin release assay (SRA).²⁷³⁻²⁷⁶

A high suspicion of HIT or a diagnosis of HIT should lead to the immediate discontinuation of heparin/LMWH anticoagulation and the discontinuation of overlap warfarin therapy.^{275,276,280} Patients with HIT should receive an alternative form of anticoagulation because of the high incidence of thrombosis associated with the discontinuation of the standard anticoagulants.^{275,276,280} The most commonly recommended alternative agents include the direct thrombin inhibitors argatroban^{275,280-282} or lepirudin.²⁸³⁻²⁸⁶ Both agents are administered by an IV infusion. Lepirudin undergoes renal excretion and may be used by patients who have hepatic insufficiency.^{275,280} Lepirudin has the disadvantage that with prolonged use, antibodies develop, and anaphylaxis may occur.²⁸⁷ Although not approved by the FDA for this indication, some medical centers use bivalirudin instead of lepirudin for the treatment of HIT. Argatroban has partial hepatic excretion, so it is the preferred agent in patients who have renal failure, though significant hepatic insufficiency contraindicates its use.^{275,280} Overlapping therapy with VKA should not be initiated until the platelet count has recovered. The alternative antithrombotic agent should be continued until the platelet count returns to $\geq 100 \times 10^9/L$ and an adequate duration of oral therapy has occurred (e.g., INR therapeutic for two consecutive days on VKA therapy).²⁷⁵ Argatroban by itself increases the INR beyond that observed with VKA therapy alone, and specific recommendations exist for INR monitoring in this setting.²⁸² Although it has been less studied, fondaparinux has been used as an alternative antithrombotic agent in HIT patients, and many clinicians prefer the use of the

subcutaneous, fixed doses of this agent^{288,289} over the adjusted-dose intravenous direct thrombin inhibitors. Limited data exist regarding use of the newer oral non-VKA anticoagulants in patients who have HIT/HITT.²⁹⁰

Nonpharmacologic Therapies

Inferior Vena Cava Filter

Insertion of an inferior vena cava (IVC) filter is indicated for patients who have an acute VTE and an absolute contraindication to anticoagulant therapy.^{1,2} If the contraindication resolves, the patient should receive a standard course of anticoagulation. IVC filters are also indicated for those rare patients who have an objectively documented recurrent VTE during adequate anticoagulant therapy.^{1,2}

IVC filters help prevent embolism of pelvic or lower extremity DVT. Studies have shown a decreased risk of PE, an increased risk of DVT, and no effect on overall mortality in patients with proximal DVT who had treatment with an IVC filter and anticoagulation, in comparison to sole treatment with anticoagulation.²⁹¹⁻²⁹³

If a transient contraindication to anticoagulation due to a temporary high risk of bleeding occurs, a patient with an acute VTE should have a retrievable IVC filter placed.²⁹⁴⁻²⁹⁶ Several types of removable/retrievable IVC filters exist and can provide a temporary physical barrier against emboli from the lower extremities; however, they likely increase the risk of DVT.²⁹¹ After the contraindication to anticoagulation resolves, the retrievable filter should be removed. Thus, filter removal requires a second procedure. Retrievable IVC filters should be removed within the manufacturer's recommended time window, and when they are no longer indicated to prevent long-term complications (e.g., recurrent DVT), some retrievable filters should not become permanent because of risks of filter-related complications (e.g., strut fracture with possible embolization, migration, penetration of the vein wall, tilting, and thrombosis).^{297,298}

A recent study showed that a retrievable IVC filter plus anticoagulation in hospitalized patients who have PE associated with DVT and at least one other severity risk factor did not reduce the risk of symptomatic recurrent PE over 3 months of follow-up in comparison to anticoagulation alone.²⁹⁹ Thus, retrievable IVC filters should not be part of routine VTE management.

Catheter-Directed Treatment

In patients who have RV failure and large, central embolic burden, the concept of mechanically reestablishing pulmonary blood flow has great appeal. However, catheter-based mechanical clot treatment, with (i.e., pharmacomechanical treatment) or without local thrombolytic therapy, lacks strong data supporting a greater efficacy/safety profile over pharmacologic therapy alone for treating submassive/intermediate-risk^{167,301-304} or massive/high-risk³⁰¹ PE.^{1,2} Catheter-based interventions that use lytic therapy have not been adequately compared to lytic therapy alone. Catheter-based interventions provide another potential treatment option for patients with massive /high-risk PE who have contraindications to anticoagulation and thrombolytic agents.^{1,2}

Surgical Embolectomy

Surgical embolectomy has a role in patients who have massive/high-risk PE and a contraindication to thrombolytic therapy or failed thrombolytic therapy.^{1,2} Depending on center expertise, catheter-based interventions should be considered as a potential alternative option to surgical embolectomy.^{1,2}

Surgical embolectomy for acute PE, often reserved for patients who fall within the most severe spectrum of those with massive/high-risk PE, has had high morbidity and mortality (25%) rates.³⁰⁵⁻³⁰⁷ However, surgical embolectomy on cardiopulmonary bypass with the heart in arrest for the rescue of patients remaining unstable despite IV thrombolytic therapy has had reasonable success.¹⁶⁴ In a series of patients with major PE in whom thrombolysis failed to improve clinical status, those who underwent surgical embolectomy had fewer recurrent PEs and a trend toward fewer deaths significantly compared to those who

received repeat IV thrombolysis.¹⁶⁵ Patients who have a right heart thrombus that straddles the interatrial septum via a patent foramen ovale/atrial septal defect should be considered for surgical embolectomy.³⁰⁸ Embolectomy for free-floating right heart thrombus remains controversial.³⁰⁹ Taken together, these studies suggest surgical embolectomy in expert centers has an important role in PE treatment in selected patients who fail or have a contraindication to aggressive medical therapy. Center-specific protocols for the management of such cases may improve outcomes.^{166,310}

MONITORING AND FOLLOW-UP

Patients in the ICU who undergo anticoagulation, thrombolytic therapy, catheter-based therapy, or surgery for acute PE should be closely monitored for nonimprovement or decompensation associated

with the PE or its treatment (e.g., bleeding, HIT/HITT). Monitoring of pulmonary, cardiovascular, renal/volume and hematologic status will assist with management. Regarding laboratory testing, patients who receive UFH, argatroban, or lepirudin should have close monitoring of the aPTT. Anticoagulated patients should initially undergo platelet count and hemoglobin monitoring. HIT-Ab testing may be warranted with the initial thromboembolic event, with a PLT count drop, or with a recurrent thrombotic event. Hypercoagulable testing is typically not indicated in the acute setting. The need for procedures and surgical interventions may lead to PE management changes. The need to temporarily discontinue or change anticoagulant therapy will require cautious timing of drug and dose changes. Hemodynamically stable patients who have acute PE should undergo additional testing if hemodynamic instability develops (see Fig. 71-3), and thrombolytic therapy should be considered for PE-associated deterioration.

The most recent guidelines from the ACCP for prevention of venous thromboembolism.
- Mookadam F, Jiamsripong P, Goel R, Warsame TA, Emani UR, Khandheria BK. Critical appraisal on the utility of echocardiography in the management of acute pulmonary embolism. Cardiol Rev 2010;18(1):29-37.
A critical review of the utility of echocardiography in the management of acute pulmonary embolism.
- Ceriani E, Combescuru C, Le Gal G, et al. Clinical prediction rules for pulmonary embolism: a systematic review and meta-analysis. J Thromb Haemost 2010, Feb 9. [Epub ahead of print].
Clinical prediction rules have become a standard component for the diagnosis of VTE. This is a systematic review of the various prediction rules for the diagnosis of PE.
- Stein P, Hull RD, Patel K, et al. D-dimer for the exclusion of acute venous thrombosis and pulmonary embolism. A systematic review. Ann Intern Med 2004;140(8):589-602.
This paper presents an exhaustive review of the D-dimer test for the exclusion of VTE, indicating that the ELISA D-dimer assay is the preferable test.
- Stein PD, Woodard PK, Weg JG, et al. Diagnostic pathways in acute pulmonary embolism: recommendations of the PIOPED II Investigators. Am J Med 2006;119(12):1048-1055.
Recommended diagnostic pathways for acute PE from the PIOPED II Investigators.
- Kearon C, Kahn SR, Agnelli G, Goldhaber S, Raskob GE, Comerota AJ. Antithrombotic therapy for venous thromboembolic disease. American College of Chest Physicians Evidence-Based Clinical Practice Guidelines. 8th ed. Chest 2008;133(6 Suppl.):454S-545S.
The most recent ACCP Guidelines for the treatment of VTE.
- Hirsh J, Bauer KA, Donati MB, Gould M, Samama MM, Weitz JI. Parenteral anticoagulants: American College of Chest Physicians Evidence-Based Clinical Practice Guidelines. 8th ed. Chest 2008;133(6 Suppl.):141S-159S.
This paper, part of the ACCP Supplement on Anti-thrombotic and Thrombolytic Therapy, reviews parenteral anticoagulants including heparin, low-molecular-weight heparin, fondaparinux, and the direct thrombin inhibitors.
- Warkentin TE, Greinacher A, Koster A, et al. Treatment and prevention of heparin-induced thrombocytopenia: American College of Chest Physicians Evidence-Based Clinical Practice Guidelines. 8th ed. Chest 2008;133(6 Suppl.):340S-380S.
A review of the prevention and treatment of heparin-induced thrombocytopenia by two of the leading investigators in the area.
- Gould MK, Dembitzer AD, Doyle RL, Hastie TJ, Garber AM. Low-molecular-weight heparins compared with unfractionated heparin for treatment of acute deep venous thrombosis. A meta-analysis of randomized, controlled trials. Ann Intern Med 1999;130(10):800-809.
One of the best meta-analyses comparing LMWH and UFH for the treatment of acute DVT; indicates a significant advantage for LMWH in the reduction of major bleeding and mortality.
- Ansell J, Hirsh J, Hylek E, Jacobson A, Crowther M, Palareti G. Pharmacology and management of the vitamin K antagonists: American College of Chest Physicians Evidence-Based Clinical Practice Guidelines. 8th ed. Chest 2008;133(6 Suppl.):160S-198S.
A comprehensive review of the pharmacology and management of warfarin as part of the ACCP Supplement on Antithrombotic and Thrombolytic Therapy.
- Douketis JD, Berger PB, Dunn AS, et al. The perioperative management of antithrombotic therapy: American College of Chest Physicians Evidence-Based Clinical Practice Guidelines. 8th ed. Chest 2008;133(6 Suppl.):299S-339S.
A review of bridging therapy for the interruption of warfarin therapy in patients requiring surgical procedures, with guidelines from the ACCP Panel.
- Young T, Tang H, Aukes J, et al. Vena cava filters for the prevention of pulmonary embolism. Cochrane Database Syst Rev 2007;(4):CD0006212.
A Cochrane review of the role of vena cava filters for the prevention of PE.

Pulmonary hypertension (PH) is defined as a pulmonary artery mean pressure (PAPm) of 25 mm Hg or greater and may be precapillary or postcapillary in etiology. Postcapillary causes include processes affecting the left side of the heart (e.g., left ventricular systolic or diastolic dysfunction, mitral stenosis or regurgitation, and aortic valvular disease) or, more rarely, the pulmonary veins (pulmonary veno-occlusive disease). Management of postcapillary PH typically involves treating the underlying left-sided cardiac process. Medications used to treat precapillary PH are often not only ineffective for postcapillary PH but may in fact be harmful, potentially leading to the development of pulmonary edema or systemic hypotension.

Precapillary PH, or pulmonary arterial hypertension (PAH), can be idiopathic (IPAH, previously known as *primary PH* [PPH]) or may occur in association with a variety of underlying disease processes, such as collagen vascular disease, portal hypertension, congenital systemic-to-pulmonary shunts, drug or toxin exposure, or human immunodeficiency virus (HIV) infection.¹ IPAH is principally a disease of young women, but it can affect all age groups and both sexes. A genetic predisposition may underlie a substantial proportion of these cases and is referred to as heritable pulmonary arterial hypertension (HPAH).²⁻⁸

Initial therapy may be directed at an underlying cause or contributing factors such as using continuous positive airway pressure (CPAP) and supplemental oxygen for PH associated with obstructive sleep apnea. Following the identification and treatment of underlying associated disorders and contributing factors, specific therapy for PAH should be considered. IPAH carried a very poor prognosis (median survival rate of approximately 2.8 years from the date of diagnosis) through the mid-1980s. Subsequently, a number of therapeutic options have been developed, and 12 have been approved by the U.S. Food and Drug Administration (FDA), falling into three classes of drugs: (1) prostacyclins, including intravenous epoprostenol, treprostinil (subcutaneously, intravenously, by inhalation, and orally), and inhaled iloprost; (2) endothelin receptor antagonists (bosentan, ambrisentan, and macitentan); and (3) drugs acting on the nitric oxide pathway, including the phosphodiesterase (PDE) type-5 inhibitors, sildenafil and tadalafil, and the guanylate cyclase activator, riociguat.

■ DIAGNOSIS

Symptoms, Signs, and Clinical History

As a result of the insidious onset of symptoms, PAH is often advanced at the time of diagnosis. Dyspnea upon exertion is the most common presenting symptom, but it is sometimes attributed to deconditioning or another cardiorespiratory ailment. Chest pain, mimicking angina pectoris, may also occur. Patients with advanced disease may present with syncope or signs and symptoms of right-sided heart failure, including lower extremity edema, jugular venous distention, and ascites.

The clinical history should focus initially on the exclusion of underlying causes of PH. Important clues to an underlying condition might include a previous history of a heart murmur, deep venous thrombosis (DVT) or pulmonary embolism, Raynaud's phenomenon, arthritis, arthralgias, rash, heavy alcohol consumption, hepatitis, heavy snoring, daytime hypersomnolence, morning headache, and morbid obesity. A careful family history should be obtained. Medication exposure, particularly to appetite suppressants and amphetamines, should be noted.

Cocaine is a powerful vasoconstrictor and may contribute to the development of PH. Intravenous drug abuse has been associated with the development of PAH.

Physical Examination

Signs of PAH may not become apparent until late in the disease. Findings, such as an accentuated second heart sound, a systolic murmur over the left sternal border, jugular venous distention, peripheral edema, and ascites might suggest the presence of PH and right ventricular dysfunction. Associated systemic diseases, such as collagen vascular disease or liver disease may also become apparent during routine examination.

Laboratory Evaluation

Laboratory evaluation can provide important information in detecting associated disorders and contributing factors. A collagen vascular screen including antinuclear antibodies, rheumatoid factor, and erythrocyte sedimentation rate is often helpful in detecting autoimmune disease, although some patients with IPAH will have a low-titer positive antinuclear antibody test.⁹ The scleroderma spectrum of disease, particularly limited scleroderma, or the CREST syndrome (e.g., calcinosis, Raynaud's phenomenon, esophageal dysfunction, sclerodactyly, and telangiectasias), has been associated with an increased risk of the development of PAH.^{10,11} Liver function tests (e.g., aspartate aminotransferase, alanine aminotransferase, and alkaline phosphatase) may be elevated in patients with right ventricular failure and passive hepatic congestion but may also be associated with underlying liver disease. Liver disease with portal hypertension has been associated with the development of PH. Thyroid disease may occur with increased frequency in patients with IPAH and should be excluded with thyroid function testing.¹² HIV testing and hepatitis serologic studies should be performed. Routine laboratory studies, such as complete blood cell count, complete metabolic panel, prothrombin time, and partial thromboplastin time are recommended during the initial evaluation and as indicated to monitor the patient's long-term clinical status.

Echocardiography

Doppler echocardiography is useful in assessing the severity of PH and detecting left-sided heart disease. Findings may include the enlargement of the right ventricle, flattening of the interventricular septum, and compression of the left ventricle. Bubble contrast echocardiography may detect a right-to-left shunt, but exclusion of a left-to-right intracardiac shunt may require cardiac catheterization with an oximetry series. Echocardiography may be useful as part of a long-term follow-up,^{13,14} although not all patients have suitable echocardiographic windows.

Radiographic Evaluation and Exclusion of Thromboembolic Disease

Chest radiography may reveal an enlargement of the central pulmonary vessels and evidence of right ventricular enlargement. Evidence of parenchymal lung disease may also be apparent. When parenchymal lung disease is suspected, pulmonary function testing and high-resolution computed tomography (CT) of the chest may be indicated.

Ventilation/perfusion (V/Q) lung scanning should be performed in an attempt to exclude chronic recurrent pulmonary thromboembolic disease, which is among the most preventable and treatable causes of PH. Diffuse mottled perfusion can be seen in IPAH, whereas larger segmental and subsegmental mismatched defects are suggestive of chronic recurrent pulmonary thromboembolic disease. Intermediate results on V/Q lung scanning may require pulmonary arteriography to obtain a definitive diagnosis. Although contrast medium-enhanced CT has been popularized recently for the diagnosis of acute pulmonary thromboembolic disease, there is limited experience with this technique for this particular condition. Accordingly, we recommend caution at present in using contrast-enhanced CT to exclude chronic recurrent thromboembolic disease.

Pulmonary Function Testing

Pulmonary function testing is indicated to detect underlying parenchymal lung disease. The diffusing capacity is often reduced in pulmonary vascular disease, consistent with impaired gas exchange.

Right-Sided Heart Catheterization and Vasoreactivity Testing

Right-sided heart catheterization remains an important part of the evaluation. Left-sided heart dysfunction and intracardiac shunts can be excluded, the degree of PH can be accurately quantified, and cardiac output can be measured. Pulmonary vascular resistance can then be calculated. Acute pulmonary vasoreactivity can be assessed using a short-acting agent, such as prostacyclin (epoprostenol), inhaled nitric oxide, or intravenous adenosine.¹ The consensus definition of a positive acute vasodilator response in a PAH patient is a fall of PAPm of at least 10 mm Hg to ≤ 40 mm Hg, with an increased or unchanged cardiac output. The primary objective of acute vasodilator testing in patients with PAH is to identify patients who might be effectively treated with oral calcium channel blockers. The acute response to a short-acting agent such as prostacyclin has been shown to be predictive of the response to a calcium channel blocker.¹⁴ Unstable patients or those in severe right-sided heart failure who would not be candidates for treatment with calcium channel blockers need not undergo vasodilator testing.

TREATMENT

General Care

Warfarin, Oxygen, Diuretics, Digoxin, and Vaccination

Improved survival has been reported with oral anticoagulation in IPAH.^{15,16} The target International Normalized Ratio (INR) in these patients is 1.5 to 2.5. Anticoagulation of patients with PAH due to other underlying processes, such as scleroderma or congenital heart disease, is controversial. Generally, patients with PAH treated with chronic intravenous epoprostenol are anticoagulated in the absence of contraindications, owing in part to the additional risk of catheter-associated thrombosis.

Hypoxemia is a pulmonary vasoconstrictor and can contribute to the development or progression of PAH. It is generally considered important to maintain oxygen saturations greater than 90% at all times. Supplemental oxygen use is more controversial in patients with Eisenmenger physiology but may decrease the need for phlebotomy and potentially reduce the occurrence of neurologic dysfunction and complications.

Diuretics are indicated in patients with evidence of right ventricular failure and volume overload (i.e., peripheral edema and ascites). Careful dietary restriction of sodium and fluid intake is important in the management of patients with PAH with right-sided heart failure. Rapid and excessive diuresis may produce systemic hypotension, renal

insufficiency, and syncope. Serum electrolytes and measures of renal function should be followed closely in patients receiving diuretic therapy.

Although not extensively studied in PAH, digitalis is sometimes utilized in refractory right ventricular failure or atrial dysrhythmias. Drug levels should be followed closely, particularly in patients with impaired renal function.

Because of the potentially devastating effects of respiratory infections in PAH, immunization against influenza and pneumococcal pneumonia is recommended.

Calcium Channel Blockers

Patients with IPAH who respond to vasodilators and calcium channel blockers¹⁵ generally have improved survival. Unfortunately, this tends to represent a relatively small proportion of patients, comprising fewer than 20% of IPAH patients and even fewer patients with other causes of PAH.

Prostanoids

Prostacyclin, a metabolite of arachidonic acid produced primarily in the vascular endothelium, is a potent systemic and pulmonary vasodilator that also has antiplatelet aggregatory effects. A relative deficiency of endogenous prostacyclin may contribute to the pathogenesis of PAH.¹⁷

Epoprostenol. Epoprostenol therapy is complicated by the need for continuous intravenous infusion. The drug is unstable at room temperature and is generally best kept cold before and during infusion. It has a very short half-life in the bloodstream (<6 minutes), is unstable in an acidic pH, and cannot be taken orally. Because of the short half-life, the risk of rebound worsening with abrupt or inadvertent interruption of the infusion and its effects on peripheral veins, it should be administered through an indwelling central venous catheter. Common side effects of epoprostenol therapy include headache, flushing, jaw pain with initial mastication, diarrhea, nausea, a blotchy erythematous rash, and musculoskeletal aches and pain (predominantly involving the legs and feet). These tend to be dose dependent and often respond to a cautious reduction in dose. Severe side effects can occur with an overdose of the drug. Acutely, overdosage can lead to systemic hypotension. Chronic overdosage can lead to the development of a hyperdynamic state and high-output cardiac failure.¹⁸ Abrupt or inadvertent interruption of the epoprostenol infusion should be avoided because this may lead to a rebound worsening of PH, with symptomatic deterioration and even death. Other complications of chronic intravenous therapy with epoprostenol include line-related infections (which can range from small exit-site reactions to tunnel infections and cellulitis), bacteremic infections with sepsis), catheter-associated venous thrombosis, systemic hypotension, thrombocytopenia, and ascites.

Treprostinil. Treprostinil, a prostacyclin analog with a half-life of 3 hours, is stable at room temperature. An international placebo-controlled, randomized trial demonstrated that treprostinil improved exercise tolerance, although the 16-meter median difference between treatment groups in 6-minute walking distance was relatively modest.¹⁹ Treprostinil also improved hemodynamic parameters. Common side effects included headache, diarrhea, nausea, rash, and jaw pain. Side effects related to the infusion site were common (85% of patients complained of infusion-site pain, and 83% had erythema or induration at the infusion site). Treprostinil is also approved for intravenous delivery based on bioequivalence with the subcutaneous route and is also approved as an inhaled preparation administered in doses of 6 to 54 μ g, 4 times daily.²⁰

Inhaled Iloprost. Iloprost is a chemically stable prostacyclin analog with a serum half-life of 20 to 25 minutes.²¹ In IPAH, acute inhalation of iloprost resulted in a more potent pulmonary vasodilator effect than acute nitric oxide inhalation.^{21,22} In uncontrolled and controlled studies of iloprost for various forms of PAH,^{23,24} inhaled iloprost at a total daily dose of 30 to 200 μ g divided in 6 to 12 inhalations improved functional class, exercise capacity, and pulmonary

hemodynamics for periods up to 1 year of follow-up. The treatment was generally well tolerated except for mild coughing, minor headache, and jaw pain in some patients. The most important drawback of inhaled iloprost is the relatively short duration of action, requiring the use of 6 to 9 inhalations per day.

Beraprost. Beraprost sodium is an orally active prostacyclin analog²⁵ that is absorbed rapidly under fasting conditions. It has been evaluated in peripheral vascular disorders, such as intermittent claudication,²⁶ Raynaud's phenomenon, and digital necrosis in systemic sclerosis,²⁷ with variable results. Although several small, open, uncontrolled studies reported beneficial hemodynamic effects with beraprost in patients with IPAH, two randomized double-blind, placebo-controlled trials have shown only modest improvement and suggest that beneficial effects of beraprost may diminish with time.^{28,29}

Endothelin Receptor Antagonists

Endothelin-1 is a vasoconstrictor and a smooth muscle mitogen that may contribute to the pathogenesis of PAH. Endothelin-1 expression, production, and concentration in plasma^{30,31} and lung tissue³² are elevated in patients with PAH, and these levels are correlated with disease severity.

Bosentan. Bosentan is a dual endothelin receptor blocker that has been shown to improve pulmonary hemodynamics and exercise tolerance and delay the time to clinical worsening in PAH patients falling into NYHA Classes III and IV.^{33,34} The most frequent and potentially serious side effect with bosentan is dose-dependent abnormal hepatic function (as indicated by elevated levels of alanine aminotransferase and aspartate aminotransferase). Because of the risk of potential hepatotoxicity, the FDA requires that liver function tests be performed at least monthly in patients receiving this drug. Bosentan may also be associated with the development of anemia, which is typically mild. Hemoglobin and hematocrit should also be checked regularly.

Ambrisentan. Ambrisentan is a selective endothelin-A receptor antagonist that has been shown to be effective in PAH.³⁵ The typical doses are 5 to 10 mg daily.

Macitentan. Macitentan is a dual endothelin receptor antagonist that has been shown to reduce disease progression in PAH and is associated with a low incidence of liver function abnormality and peripheral edema. The usual dose is 10 mg daily.

PDE Inhibitors

PDEs are enzymes that hydrolyze the cyclic nucleotides, cyclic adenosine monophosphate (cAMP) and cyclic guanosine monophosphate (cGMP), as well as limit the intracellular signaling. Drugs that selectively inhibit cGMP-specific PDEs (or PDE type-5 inhibitors) augment the pulmonary vascular response to endogenous or inhaled nitric oxide in models of PH.³⁶⁻³⁷ PDE5 is strongly expressed in the lung, and PDE5 gene expression and activity are increased in chronic PH.³⁸

Sildenafil. Sildenafil is a potent specific PDE5 inhibitor that is approved for erectile dysfunction. Recent reports have shown that sildenafil blocks acute hypoxic pulmonary vasoconstriction in healthy adult volunteers and acutely reduces PAPm in patients with PAH.³⁹ In comparison with inhaled nitric oxide, sildenafil produces similar reductions in PAPm. However, unlike nitric oxide, sildenafil also had apparent systemic hemodynamic effects. When combined with inhaled nitric oxide, sildenafil appears to augment and prolong the effects of inhaled nitric oxide,⁴⁰ and it appears to prevent rebound pulmonary vasoconstriction after acute withdrawal of inhaled nitric oxide.⁴¹ Several randomized studies have demonstrated sildenafil's efficacy in PAH, both as monotherapy and in combination with epoprostenol.^{42,43} Sildenafil treatment in animal models with experimental lung injury reduced PAP, but gas exchange worsened owing to impaired V/Q mismatch.^{44,45} Accordingly, caution is advised when using sildenafil to treat PH in patients with severe lung disease.

Tadalafil. Tadalafil, another PDE5 inhibitor previously approved for erectile dysfunction, is approved for the treatment of PAH based on a randomized clinical trial.⁴⁶ Side effects appear to be similar to sildenafil. The recommended dosage is 40 mg daily.

Riociguat. Riociguat is a novel agent whose mechanism of action is the activation of soluble guanylate cyclase, thereby potentiating the vasodilatory action of cyclic GMP, the mediator through which nitric oxide exerts its vascular effects. Riociguat is approved for the treatment of both PAH and inoperable chronic thromboembolic PH (CTEPH) and is the only drug therapy that has regulatory approval for the latter condition.

Combination Therapy

The AMBITION trial demonstrated that treatment-naïve PAH patients treated with initial combination therapy of ambrisentan and tadalafil had a significant reduction in the relative risk of disease progression.^{46a} Additionally, greater reductions in N-terminal pro-brain natriuretic peptide (a biomarker of cardiac overload) and greater improvements in exercise capacity compared with patients who were treated with monotherapy using either agent alone were also observed. Based on these findings, many experienced clinicians have begun initiating PAH treatment with combination therapy.

Nitric Oxide

Nitric oxide contributes to the maintenance of normal vascular function and structure. It is particularly important in the normal adaptation of the lung circulation at birth, and impaired nitric oxide production may contribute to the development of neonatal PH. L-Arginine is the sole substrate for nitric oxide synthase and thus is essential for nitric oxide production.

Inhaled Nitric Oxide. Inhaled nitric oxide has been shown to have potent and selective pulmonary vasodilator effects during brief treatment of adults with IPAH.⁴⁷ It is a potent pulmonary vasodilator in newborns with PH (persistent PH of the newborn [PPHN]), children with congenital heart disease, and patients with postoperative PH, acute respiratory distress syndrome, or undergoing lung transplantation.⁴⁸ It is of substantial benefit in PPHN, decreasing the need for support with extracorporeal membrane oxygenation (ECMO).⁴⁹ Although inhaled nitric oxide has been used in diverse clinical settings, especially in intensive care medicine, FDA approval for this therapy is limited to newborns with hypoxemic respiratory failure at this time.

In chronic PAH, the use of inhaled nitric oxide has been primarily for acute testing of pulmonary vasoreactivity during cardiac catheterization¹ (see earlier) or for acute stabilization of patients during deterioration.

Lung Transplantation

Lung transplantation for PAH is generally reserved for patients whose condition is failing despite the best available medical therapy. Whereas lung transplantation is challenging in general, it is even more so in the group of patients with PAH.⁵⁰ Worldwide, overall survival is approximately 77% at 1 year and 44% at 5 years.⁵¹ Survival in PAH patients undergoing lung transplantation is 66% to 75% at 1 year (one center has reported 1- and 5-year actuarial survival of 75% and 57%, respectively).⁵² The higher early mortality in PAH patients may be related to higher anesthetic and operative risks, the need for cardiopulmonary bypass,⁵³ and the increased occurrence of postoperative reperfusion pulmonary edema in patients with PAH undergoing single lung transplantation. In this situation, reperfusion pulmonary edema may be aggravated by the increased blood flow to the newly engrafted lung. In addition, V/Q mismatching can be particularly severe.⁵⁴ Most centers therefore seem to prefer bilateral lung transplantation for patients with PAH.⁵⁵ The timing of transplantation in PAH is challenging. It is probably most useful for patients exhibiting clear evidence of deterioration, such as the decline in functional capacity and the development of right-sided heart failure despite maximal medical therapy.

Special Situations in the Intensive Care Unit

DVT Prophylaxis

Patients with PAH are likely at an increased risk for the occurrence of DVT and are certainly at increased risk for poor outcomes as a

consequence of the development of DVT. Patients with PAH are prone to a more sedentary lifestyle and to chronic venous congestion of the lower extremities owing to increased right-sided cardiac filling pressures. Hospitalization in the intensive care unit (ICU), often with discontinuation of anticoagulation in anticipation of invasive procedures, likely places these patients at even higher risk for DVT. For these reasons, meticulous attention must be paid to DVT prophylaxis.

Procedures and Surgery

Procedures and surgery in patients with PAH can be associated with substantially increased operative and perioperative risks. In addition, appropriate precautions should be undertaken to optimize outcomes. As always, careful consideration should be given to whether an invasive procedure is absolutely necessary.

Vasovagal Events

Patients with severe PAH are particularly prone to vasovagal events, which can lead to severe consequences including syncope, cardiopulmonary arrest, and death. Pain, nausea, vomiting, or even a bowel movement can lead to a vasovagal event in patients with severe PAH. Cardiac output may be particularly dependent on heart rate in this situation. Moreover, the bradycardia and systemic vasodilatation that accompany a vasovagal event can result in an abrupt decrease in systemic arterial pressure. Therefore, patients should be closely monitored for their heart rate during invasive procedures, with readily available atropine or a similar agent.

Avoidance of Hypoxemia and Hypercarbia

Hypoxemia and hypercarbia are both pulmonary vasoconstrictors and can contribute to the worsening of PH. Oversedation can lead to ventilatory insufficiency and precipitate clinical deterioration. Caution should be utilized in laparoscopic procedures in which carbon dioxide is used for abdominal insufflation, because absorption can lead to hypercarbia. The induction of anesthesia and intubation for surgical procedures can be a particularly high-risk period for patients with PAH. This is because they are at risk for vagal events, hypoxemia, hypercarbia, and shifts in intrathoracic pressure with associated changes in cardiac filling pressures.

Pregnancy

The hemodynamic changes in pregnancy are substantial and volume shifts occur immediately postpartum, with cardiac filling pressures increasing as a result of decompression of the vena cava and the return of uterine blood into the systemic circulation. The changes induced by pregnancy impose a significant hemodynamic stress in women with IPAH, leading to an estimated 30% to 50% mortality rate.^{56,57} A meta-analysis of the outcome of pulmonary vascular disease and pregnancy reported a maternal mortality rate of 36% in Eisenmenger's syndrome, 30% in IPAH, and 56% in secondary PH.⁵⁸ Because of high maternal and fetal morbidity and mortality rates, most experts recommend effective contraception and early fetal termination in the event of pregnancy.⁵⁹ There have been case reports of successful treatment of pregnant IPAH patients with chronic intravenous epoprostenol,⁶⁰⁻⁶² inhaled nitric oxide,⁶³⁻⁶⁵ and oral calcium channel blockers.⁶⁶ Endothelin receptor antagonists are classified as teratogenic and should be avoided in this setting. In general, management includes early hospitalization for monitoring, supportive therapy with cautious fluid management, supplemental oxygen, diuretics, and dobutamine, as needed. The use of a pulmonary artery catheter for close hemodynamic monitoring and titration of vasodilator and cardiotonic therapy also has been recommended. Recommendations regarding the mode of delivery remain controversial.

Portopulmonary Hypertension

Patients with chronic liver disease have an increased prevalence of pulmonary vascular disease.^{67,68} Two forms of pulmonary vascular disease can complicate chronic liver disease: (1) the hepatopulmonary syndrome and (2) portopulmonary hypertension. Both tend to occur

in patients with chronic, late-stage liver disease, and each may increase the risk associated with liver transplantation.

Hypoxemia and intrapulmonary shunting characterize hepatopulmonary syndrome. Shunting may be manifest echocardiographically by the late appearance (after three to five cardiac cycles) of bubble contrast in the left side of the heart. Treatment is generally supportive, with supplemental oxygen. The syndrome may improve in some patients after liver transplantation. Severe hepatopulmonary syndrome may increase the risk associated with undergoing liver transplantation.

Portopulmonary hypertension occurs in patients with chronic, late-stage liver disease and portal hypertension.⁶⁹ Portopulmonary hypertension often differs hemodynamically from IPAH, and these differences may affect the approach to therapy. Patients with portopulmonary hypertension have lower pulmonary arterial diastolic and mean pressures, higher cardiac outputs, and lower pulmonary and systemic resistances.⁷⁰ Later-stage patients may develop hemodynamic findings similar to those of patients with IPAH, and this group may have a poorer prognosis and be at higher risk with attempted liver transplantation. It is occasionally possible to make a borderline candidate for liver transplantation acceptable through aggressive treatment of the PAH. Supplemental oxygen should be used as needed to maintain saturations $\geq 91\%$ at times. Diuretic therapy should be utilized to control volume overload, edema, and ascites. Anticoagulant therapy has not been carefully studied in this population and should likely be avoided in patients with significant coagulopathy due to impaired hepatic synthetic capability and in patients at increased risk of bleeding due to gastroesophageal varices. There have been a number of case reports and small case series describing the use of intravenous epoprostenol for treatment of portopulmonary hypertension.⁷¹⁻⁷⁵ Interestingly, some patients may demonstrate improvement in their PH following liver transplantation.⁷⁶ Other patients may develop worsening of their PH well after transplantation. It may be possible to wean an occasional patient off epoprostenol after liver transplantation. This should probably be done very gradually under close observation. The development of increasing dyspnea, fluid retention, or fatigue should prompt the reevaluation and reinstitution of epoprostenol if necessary. Because of its potential for hepatotoxicity, caution is advised in using the oral endothelin antagonists in this population.

KEY POINTS

1. The evaluation of patients with pulmonary hypertension (PH) is directed at the detection of underlying contributing factors and associated conditions such as left-sided cardiac dysfunction, underlying congenital heart disease, pulmonary thromboembolic disease, collagen vascular disease, parenchymal lung disease, obstructive sleep apnea, liver disease, amphetamine or appetite suppressant use, intravenous drug abuse, or human immunodeficiency virus (HIV) infection.
2. Patients with severe PH are particularly prone to vasovagal events, and when these occur they can lead to severe consequences, including syncope, cardiopulmonary arrest, and death.
3. Hypoxemia and hypercarbia are both pulmonary vasoconstrictors and can contribute to the worsening of pulmonary hypertension.
4. The induction of anesthesia and intubation for surgical procedures can be a particularly high-risk time for patients with PAH, as they are at risk for vagal events, hypoxemia, hypercarbia, and shifts in intrathoracic pressure with associated changes in cardiac filling pressures.

ANNOTATED REFERENCES

Pneumothorax is defined as air within the pleural space and typically results from injury to the visceral pleura or mediastinum. Pneumothorax is commonly seen in the intensive care unit (ICU) due to iatrogenic causes such as central line placement or barotrauma in mechanically ventilated patients. Tension pneumothorax can be seen in 4% to 15% of mechanically ventilated patients in the ICU.^{1,2} In addition, patients with chronic lung diseases, cardiothoracic surgery, or trauma have an increased risk of pneumothorax. A simple pneumothorax may rapidly progress to a fatal tension pneumothorax with resultant hypoxia and/or hypotension or cardiogenic shock. Therefore, it is imperative that healthcare workers in the ICU must be able to rapidly diagnose and treat a pneumothorax.

■ PATHOPHYSIOLOGY

Pneumothorax most commonly results from a tear in the visceral pleura, but may air may also enter the pleural space from the atmosphere (trauma/iatrogenic) or via gas-producing organisms in the setting of empyema.³ Spontaneous pneumothorax is considered “primary” when there is no obvious underlying lung disease and “secondary” when there is underlying lung disease such as emphysema or cystic lung disease. Primary spontaneous pneumothorax typically occurs in tall, thin males with an “ectomorph” body habitus, and is thought to be due to increasing pleural porosity or rupture of previously unseen subpleural blebs.⁴ As patients with secondary spontaneous pneumothorax have underlying lung disease with less cardiopulmonary reserves, they typically present more acutely than those with primary spontaneous pneumothorax, which requires more urgent drainage and hospitalization is recommended.⁵ Nonspontaneous pneumothorax occurs either due to penetrating or blunt trauma, as well as iatrogenic injury of the chest wall or visceral pleura. Traumatic pneumothorax is the second most common clinical finding after chest trauma, following broken ribs. Iatrogenic pneumothorax in the ICU most often occurs after central venous access, thoracentesis, transbronchial lung biopsy, and positive pressure ventilation.⁶

The progression from a simple pneumothorax to tension pneumothorax relies on the continued escape of gas into a closed pleural space. This leads to increasing transpleural pressure, the collapse of the lung, atelectasis, and hypoxemia. As the tension pneumothorax becomes more severe, venous return is limited resulting in a fall in cardiac output and shock.

Animal studies have investigated the pathophysiology of tension pneumothorax.^{7,8,9} Proposed mechanisms contributing to tension physiology include hypoxia due to shunting of blood through the atelectatic lung, hypoventilation due to increased transpleural pressure causing reduced diaphragmatic excursion, and decreased preload from increases in intrathoracic pressure. The traditionally taught mechanism of vena cava mechanical obstruction likely plays less of a role.¹⁰ Major clinical findings may differ depending on whether the patient is spontaneously breathing or on positive pressure ventilation. Hypoxia is usually the main finding in spontaneously breathing patients. Patients with the impaired respiratory drive (needed to decrease intrathoracic pressure and increase venous return) or hypovolemia, however, may have reductions in cardiac output.

Patients on mechanical ventilation pose the highest risk for hemodynamic instability. The rate of increase in volume in the pleura space

depends on the volume/pressure being delivered and degree of pleural injury. With an increasing volume of gas entering the pleural space, a critical point is reached resulting in decreased venous return and eventual equalization of pressure within the cardiac chambers leading to a decrease in cardiac output and, ultimately, cardiac arrest.¹¹

■ DIAGNOSIS AND EVALUATION

The diagnosis of pneumothorax in critically ill patients can sometimes be made with information from the history and physical examination, noting acute onset of dyspnea or chest pain, tachycardia, hypotension, decreased breath sounds, pulsus paradoxus, and contralateral tracheal deviation. Although clinical features can be used to diagnose the presence of a pneumothorax, it should be noted that many of these findings are nonspecific and have not been a reliable indicator of pneumothorax size especially in the case of spontaneous secondary pneumothorax where severe symptoms of dyspnea can be out of proportion to the size of the pneumothorax, and underlying emphysema can cause diminished breath sounds. Acute changes in ventilatory parameters, such as a reduction in tidal volume or increase in airway pressures resulting from reduced respiratory system compliance, may be associated with pneumothorax but can also be found in other disease states and, therefore, have the potential to be misinterpreted under different clinical scenarios. As a result, radiologic imaging remains the gold standard for the diagnosis of pneumothorax.¹²

While radiographic imaging is optimal to diagnose pneumothorax, equipment may not be readily available, and therapeutic treatment (i.e., needle decompression or chest tube) may be required in unstable patients on clinical grounds prior to radiographic confirmation¹³ (Fig. 73-1).

Portable chest radiographs traditionally have been the initial diagnostic test in the ICU to diagnose a pneumothorax. Most of these radiographs in the ICU have the patient in the supine or semirecumbent position rather than an erect position.¹⁴ However, caution should be exercised when interpreting supine radiographs as the most non-dominant part of the chest (where air will collect) is in the costophrenic recess, known as the “deep sulcus sign.”¹⁵ A skin fold on chest radiograph may resemble a pneumothorax by mimicking a sharp lung edge but, in fact, represents a normal finding.¹⁶ Skin folds may be seen in elderly or obese patients and can be confirmed by a repeat radiograph in a different position. Due to the limitations of chest radiography, it is important to treat the patient and not the radiograph. In the right clinical situation with concern for tension pneumothorax, clinicians should proceed with immediate pleural evacuation to avoid further clinical decompensation. If there is doubt in regards to the findings on a chest radiograph and the patient is stable, it is advised to seek the expert opinion of the radiologist and/or further imaging with ultrasound or chest computed tomography (CT).¹⁷

CT is the gold standard test for confirming the diagnosis and size of the pneumothorax. CT also allows for assessment of underlying lung parenchyma and pleural-based lesions and can differentiate bullous disease from pneumothorax, potentially avoiding inappropriate drainage and creation of a parenchymal-pleural fistula.¹⁸ With widespread use of CT scanning, the diagnosis of occult pneumothoraces has become more common. The occult pneumothorax is defined as a pneumothorax detected via CT that was not clinically suspected or

FIGURE 73-1 ■ Different modalities for diagnosing pneumothorax. **A**, Chest x-ray. **B**, US M-mode. **C**, CT scan. **D**, Needle Aspiration. CT, computed tomography; US, ultrasound.

recognized on standard chest radiography.¹⁹ This may be more common with the increased availability of CT scans. The overall incidence of trauma patients with an occult pneumothorax ranges from 2% to 15% and can be as high as 64% in multitrauma patients.²⁰ There is controversy on how to treat patients with an occult pneumothorax on mechanical ventilation due to the potential escalation to tension pneumothorax. A multicenter randomized study in a trauma population on mechanical ventilation did not show a difference in respiratory distress between observation vs. prophylactic chest tube insertion (relative risk: 0.71; 95% confidence interval: 0.40-1.27).²¹ Ultimately, 31% of the observed patients had subsequent chest tube placement nonurgently for worsening pneumothorax on imaging without an increase in morbidity. While this single study lends support for observation of occult pneumothoraces in mechanically ventilated patients in the trauma population, further studies are needed to guide management in different populations and situations. The expert consensus remains that clinical judgment is utilized to determine if drainage is needed.²²

Thoracic ultrasound has become an increasingly accessible tool in ICU for the diagnosis of pneumothorax. There are several advantages of ultrasound over chest radiograph and CT including availability at the bedside, absence of radiation, real-time imaging, and the ability to easily perform dynamic and repeat evaluations. A recent meta-analysis has shown that ultrasound is more sensitive and specific than a standard chest radiograph for detecting pneumothorax and can be used to assess lung re-expansion following tube thoracostomy.²³ The major pitfall in ultrasound is in acquiring the skills of image acquisition and interpretation for the nonradiologist.²⁴ Another limitation may be severe subcutaneous emphysema which will limit ultrasound waves penetrating into the thoracic cavity. A study comparing ultrasound to

CT/chest radiographs for the diagnosis of occult pneumothorax showed that the use of ultrasound detected 92% of occult pneumothoraces diagnosed with CT.²⁵ Ultrasound is extremely useful in ruling out pneumothorax after pleural procedures and central line placement, negating the need and time delay for a portable radiograph.^{26,27}

Normal movement of the underlying lung with respiration produces a “sliding” or “gliding” sign, and this dynamic movement identifies the visceral pleura and lung parenchyma. Examination of the lung with ultrasound commonly shows A-lines and B-lines. A-lines are horizontal, hyperechoic lines that represent reverberation artifacts of the visceral-parietal pleural interface. B-lines, also known as comet tail artifacts, are caused by echo reverberations of the air-filled lung and appear as narrow hyperechoic raylike opacities extending from the pleural line to the edge of the ultrasound screen without the fading that moves with lung sliding. As pleural air would block the visualization of the underlying lung, the presence of B-lines and lung sliding rules out a pneumothorax with a negative predictive value of 100% in the location of the chest probe.²⁸ It is important to examine several locations on the thorax, especially the superior anterior and lateral chest wall, where air would normally accumulate. One can also fail to see lung sliding when there is contralateral mainstem intubation, pleural-parenchymal adhesions, endobronchial obstruction, or diaphragmatic paralysis. Therefore, the main utility of ultrasound for assessment of pneumothorax lies in its ability to rule out a pneumothorax. Lung ultrasound, however, can also be used to rule in pneumothorax by identifying the point where the lung separates from the chest wall. This is seen as an area where normal lung sliding meets an area where no lung sliding is seen and has been termed the *lung point*. The lung point can be visualized with both B-mode and M-mode

ultrasound and, when seen, has 100% specificity for pneumothorax.²⁹ The sensitivity of the lung point for pneumothorax is inversely proportional to the size of the pneumothorax, as a large pneumothorax would prevent the parenchyma from opposing the chest wall. Ultrasound has recently been used to follow serially the lung point and determine if the pneumothorax is enlarging.

TREATMENT

The primary goal of the management of a pneumothorax is to restore normoxia and hemodynamic stability and evacuate air from the pleural space allowing visceral and parietal pleural apposition. Although many patients with a pneumothorax can be managed with supplemental oxygen and monitoring, the majority of patients in the ICU with a pneumothorax require evacuation of pleural space.³⁰ The etiology of the pneumothorax and clinical characteristics of the patient will dictate treatment. Pneumothorax secondary to barotrauma, tension pneumothorax, and concurrent sepsis has been significantly and independently associated with an increased risk of death in the ICU.³¹ The British Thoracic Society recommends intercostal drainage for all pneumothoraces in patients on a mechanical ventilator, as well as those exhibiting signs or suspicion of tension physiology, traumatic pneumo, or hemothorax and postsurgical pneumothoraces.³² The role of needle decompression has not been well elucidated for patients on mechanical ventilation, and there are data to suggest that the therapeutic effect of this intervention may be insufficient despite proper placement and positioning.^{33,34} If needle decompression is performed, standard tube thoracostomy is usually subsequently required for definitive management.

The standard treatment for a mechanically ventilated patient with a pneumothorax or tension pneumothorax is chest tube thoracostomy.^{35,36} Optimal chest tube size remains unclear due to the difficulty in assessing the degree of visceral pleural injury. The recent British Thoracic Society guidelines recommend a small-bore tube for the initial management of pneumothorax. These tubes are associated with less pain and likely have reduced complications in patients with thrombocytopenia or coagulopathy. The risk of serious complications associated with small-bore catheters is small with a frequency of organ injury of 0.2% and a malposition rate of 0.6%. The largest risk is drain blockage, with a rate of 8.1% and is easily preventable with scheduled sterile flushing to maintain patency.³⁷ The use of ultrasound has decreased the rate of complications and should be routinely used, especially in the nonemergent placement of chest tubes.¹³ If there is a high clinical suspicion of tension pneumothorax, chest tube insertion should not be

delayed while awaiting radiographic confirmation as the delay in care may become fatal; however, in this case, it may be prudent to perform open (surgical) thoracostomy as opposed to the modified Seldinger technique in order to avoid injury to the lung, heart, or other organs should pneumothorax not be present.¹⁷

PROLONGED AIR LEAK

Prolonged or persistent air leaks (>3-5 days) may represent a more complex problem requiring additional treatment beyond chest tube insertion. Factors such as poor nutrition, the size of the pleural injury, mechanical ventilation, and medications (i.e., steroids) may hinder resolution of a pneumothorax in the ICU. Current guidelines recommend early thoracic surgery consultation with video-assisted thoracoscopic surgery (VATS) over full or partial thoracotomy as the treatment of choice for prolonged pleural air leaks. While surgical intervention has been shown to be effective and safe for persistent air leakage, most studies do not include critically ill patients.^{38,39} For patients that are not good surgical candidates, bronchoscopic treatment implanting a unidirectional endobronchial valve to isolate and close the fistula has been described to be safe and effective and is approved for a humanitarian device exemption in the United States.⁴⁰ The valves are currently indicated for the treatment of prolonged air leaks or leaks that are likely to be prolonged (defined as >7 days) following lobectomy, segmentectomy, or surgical lung volume reduction. However, many valves in the United States are placed off-label in patients with secondary spontaneous pneumothorax. The procedure is performed by first identifying the “culprit” airway via sequential bronchoscopic balloon occlusion. When the airway leading to the alveolar-pleura fistula is occluded, the amount of air leak in the chest drainage system will stop or be significantly reduced. The valve is then sized and inserted through the working channel of the flexible bronchoscope.

KEY POINTS

1. Pneumothorax is common in the ICU and may have various clinical presentations.
2. Treatment of a highly suspected tension pneumothorax should not be delayed for radiographic confirmation.
3. Occult pneumothorax on mechanical ventilation should be closely monitored if chest tube insertion is readily available.

Pneumonia is an infection of the gas-exchanging units of the lung and has a wide spectrum of clinical severity, ranging from mild outpatient illness to severe respiratory failure and sepsis. Together, pneumonia and influenza are the eighth leading cause of death in the United States and the number one cause of death from infectious diseases.^{1,2} Pneumonia in the community setting or within 48 hours following admission is termed *community-acquired pneumonia* (CAP). The “community” also includes patients with exposure to the health-care environment, and pneumonia in such patients is referred to as “health care-associated pneumonia” (HCAP). Some, but not all, patients with HCAP are at risk for infection by multidrug-resistant (MDR) pathogens and may require empiric broad-spectrum antibiotic therapy, but many can be managed with therapy directed against CAP pathogens.³ There has been increasing scrutiny by the Centers for Medicare and Medicaid Services on public reporting of outcomes and quality measures related to CAP.⁴ Pneumonia patients requiring mechanical ventilation (MV) or invasive vasopressor support are generally considered as having severe CAP (SCAP). However, there is no uniform definition for SCAP, and in the absence of these two factors, it is challenging to define severe pneumonia. Severity assessment scores may identify high-risk patients and help with site-of-care decisions, since a delay at the intensive care unit (ICU) level of care for patients with severe pneumonia is associated with worse outcomes. Biomarkers such as procalcitonin (PCT) are increasingly being used to identify patients with bacterial pneumonia and, along with severity assessment scores, may help identify high-risk patients and assist antimicrobial stewardship and de-escalation.⁵

INCIDENCE

The annual incidence of pneumonia ranges from 5 to 11 per 1000 population, and the majority of patients are treated out of the hospital.^{1,6} However, the major portion of the cost of treatment is focused on hospitalized patients, particularly those admitted to critical care units. In addition, those with comorbid illness and those of advanced age make up a large proportion of the hospitalized, critically ill CAP patients, and pneumonia in this population causes significant morbidity and mortality. Although CAP can vary from being a mild to a severe illness, very few hospitalized patients are severely ill enough to require ICU admission.^{7,8} Torres et al. specifically examined all ICU admissions over a 4-year period and noted that 10% were related to CAP; in this group, 42% were admitted directly to the ICU, 37% came to the ICU after admission to another ward, and 21% came after transfer from another hospital.⁷

The time to ICU admission may have an impact on subsequent prognosis. Woodhead et al. found that CAP accounted for 5.9% of all ICU admissions and that early admission (within 2 days of hospitalization) was associated with a lower mortality (46.3%) than late admission (>7 days in the hospital; 50.4% mortality).⁹ Recently, Restrepo and colleagues also noted a higher mortality among CAP patients admitted to the ICU after 48 hours as compared with direct admission or within 24 hours, even after adjustment for the severity of illness (47.4% vs. 23.2%, $P = 0.02$).¹⁰

The economic liability associated with CAP remains significant, at >\$17 billion annually in the United States.¹¹ Kaplan and colleagues evaluated the cost of care for 623,718 elderly patients with CAP in the United States and found that two-thirds of the population had one or

more underlying illnesses, with congestive heart failure, the most common comorbidity, present in 32%.⁸ The overall mortality rate was 10.6% but rose higher with advancing age, nursing home residence, and comorbid illness. The mean length of stay (LOS) was 7.6 days, and the costs generally paralleled the LOS but were disproportionately high for those needing MV. Kozma et al., in a study of around 1.5 million CAP admissions, showed a potential economic benefit of 2300 USD per one less day spent in the hospital per patient.¹² Other studies of CAP have reported that costs are higher for patients with comorbid illness than for those without, but in those without comorbid illness, the cost for those who died was less than for those who survived, while the opposite was true when the entire CAP population was considered.¹³

RISK FACTORS FOR DEVELOPING SCAP

In all studies of CAP, patients who were admitted to the hospital or ICU commonly had a number of coexisting illnesses, suggesting that individuals who are chronically ill have an increased risk of developing severe illness (Table 74-1).¹⁴ In studies of SCAP, serious coexisting illness was present in 46% to 66% of all patients.^{8,14,15} The common chronic illnesses in these patients are respiratory disease, cardiovascular disease, and diabetes mellitus.^{1,16,17} The most common respiratory illness in CAP patients is chronic obstructive pulmonary disease (COPD), a finding that applies to those with either the mild or severe forms of CAP.^{7,17}

Cigarette smoking has been identified as a risk factor for bacteremic pneumococcal infection, especially in younger patients with fewer comorbid conditions, and “current smoking” status is associated with a higher mortality in CAP patients than in nonsmokers or ex-smokers.^{7,18,19} Other common illnesses associated with CAP include malignancy, neurologic illness (including seizures), and acquired immune deficiency syndrome (AIDS).^{1,15} One study identified alcohol abuse as a risk factor, along with the failure to receive antibiotic therapy before hospital admission, which suggests that a delay in therapy may convert milder forms of pneumonia into a more severe illness.¹⁵ Genetic differences in the immune response may predispose certain individuals to more severe forms of infection and adverse outcomes.²⁰ Further, use of inhaled corticosteroids is related to an increased risk of developing serious pneumonia compared to placebo.²¹

PROGNOSTIC FACTORS

In recent years, there has been a trend toward increased hospitalizations in patients with a diagnosis of CAP, especially in the elderly and those with comorbid diseases, who may also have higher mortality.^{22,23} Various studies have pointed out a high inpatient mortality among CAP patients ranging from 12.1% to 24.4% and an even higher mortality in patients admitted to ICUs.^{17,24,25} Lately, investigators from the Community-Acquired Pneumonia Organization (CAPO) international cohort study reported mortality differences among patients hospitalized for CAP, with a higher frequency of deaths in Latin America (13.3%) compared with Europe (9.1%) and the United States (7.3%).²⁶

In a meta-analysis of 33,148 patients with CAP, the overall mortality rate (OR) was 13.7%, but those admitted to the ICU had a mortality rate of 36.5%. Factors associated with increased mortality in

TABLE 74-1

Risk Factors for Developing Severe Community-Acquired Pneumonia

Advanced age
 Comorbid illness (e.g., chronic respiratory illness, cardiovascular disease, diabetes mellitus, neurologic illness, renal insufficiency, malignancy)
 Cigarette smoking
 Alcohol abuse
 Absence of antibiotic therapy before hospitalization
 Failure to contain infection to its initial site of entry
 Immune suppression
 Genetic polymorphisms in the immune response

hospitalized CAP patients included male sex, pleuritic chest pain, hypothermia, systolic hypotension, tachypnea, diabetes mellitus, neoplastic disease, neurologic disease, bacteremia, leukopenia, and multilobar infiltrates.²⁵

Metersky et al. evaluated factors predicting in-hospital versus post-discharge mortality in 21,223 Medicare patients, 65 years old or older, admitted with a diagnosis of pneumonia.²⁴ The authors noted a mortality of 12.1% within 30 days of admission (52.4% of the deaths occurred during the hospital stay), and in-hospital mortality was higher in patients requiring MV on admission, and who had bacteremia, hypotension (blood pressure of less than 90 mm Hg systolic), respiratory rate of greater than 30 beats/min, pH of less than 7.35, and renal failure. Of note, the timing of death (early versus late) was unrelated to baseline patient demographic factors or comorbidities, but in-hospital mortality was related to the severity of illness.

In other studies, the clinical features that predicted a poor outcome (Table 74-2) included advanced age (>65 years), preexisting chronic illness of any type, the absence of fever on admission, respiratory rate greater than 30 breaths/min, diastolic or systolic hypotension, elevated blood urea nitrogen (BUN > 19.6 mg/dL), profound leukopenia or leukocytosis, inadequate antibiotic therapy, need for MV, hypoalbuminemia, and the presence of certain “high-risk” organisms (type III pneumococcus, *Staphylococcus aureus*, gram-negative bacilli, aspiration organisms, or postobstructive pneumonia).¹ One study of 3233 patients in Spain found that risk factors for all-cause mortality included a higher severity of illness on admission, the need for ICU care, and the presence of multilobar infiltrates. However, late mortality (after at least 3 days) was reduced if blood cultures were negative, antibiotic therapy was consistent with guidelines, and if an etiologic agent was identified.²⁷ In another prospective study of 1166 SCAP patients from 17 different countries, factors related to mortality at 28 days and at the 6-month follow-up were higher Acute Physiology and Chronic Health Evaluation (APACHE) II scores, lower hematocrit, and the need for MV, and lower pH on arterial blood gas analysis predicted early mortality.¹⁷ Other studies have noted that an elevated red cell distribution width, alone or in combination with elevated BUN \geq 30 mg/dL, was related to increased 90-day mortality and a complicated hospital course in CAP patients, likely reflecting the inflammatory suppression of erythropoiesis in severe infection.^{28,29} In general, the severity of illness on admission affected early mortality the most, while therapy-related, modifiable risk factors affected late mortality.

Prina and colleagues noted a biphasic relationship between platelet count and mortality in hospitalized CAP patients, with increased mortality once the count was outside the range of 100,000 to 400,000/mm³.^{3,30} The authors noted more respiratory complications, such as empyema and pleural effusion in patients with thrombocytosis (platelet count $\geq 4 \times 10^5$ /mm³) than in those without thrombocytosis. On the other hand, those with thrombocytopenia (platelet count $\leq 10^5$ /mm³) had higher rates of severe sepsis, septic shock, invasive MV, and ICU admission than the rest of the population. In another study, Laserna and associates observed a biphasic relationship when relating CAP mortality to arterial partial pressure of carbon dioxide (PaCO₂)

TABLE 74-2

Risk Factors for a Poor Outcome from Community-Acquired Pneumonia**PATIENT-RELATED FACTORS**

Male sex
 Absence of pleuritic chest pain
 Nonclassic clinical presentation
 Neoplastic illness
 Neurologic illness
 Age >65 years
 Family history of severe pneumonia or death from sepsis

ABNORMAL PHYSICAL FINDINGS

Respiratory rate >30 breaths/min on admission
 Systolic (<90 mm Hg) or diastolic (<60 mm Hg) hypotension
 Tachycardia (>125 beats/min)
 High fever (>40°C) or afebrile
 Confusion

LABORATORY ABNORMALITIES

Blood urea nitrogen >19.6 mg/dL
 Leukocytosis or leukopenia (<4000/mm³)
 Multilobar radiographic abnormalities
 Rapidly progressive radiographic abnormalities during therapy
 Bacteremia
 Hyponatremia (<130 mmol/L)
 Multiple organ failure
 Respiratory failure
 Hypoalbuminemia
 Thrombocytopenia (<100,000/mm³) or thrombocytosis (>400,000/mm³)
 Arterial pH <7.35
 Pleural effusion

PATHOGEN-RELATED FACTORS

High-risk organisms
 Type III pneumococcus, *Staphylococcus aureus*, gram-negative bacilli (including *Pseudomonas aeruginosa*), aspiration organisms, severe acute respiratory syndrome
 Possibly high levels of penicillin resistance (minimal inhibitory concentration of at least 4 mg/L) in pneumococcus

THERAPY-RELATED FACTORS

Delay in initial antibiotic therapy (more than 4 hours)
 Initial therapy with inappropriate antibiotic therapy
 Failure to have a clinical response to empiric therapy within 72 hours

on admission, with both hypocapnia (PaCO₂ < 35 mm Hg) and hypercapnia (PaCO₂ > 45 mm Hg) being risk factors for high 30-day mortality and a higher need for ICU admission compared with patients with a normal PaCO₂, even after excluding patients with COPD.³¹

As with other acute severe infections, any delay in treatment or admission to the ICU in patients with SCAP can lead to higher rates of complications and increased mortality.¹⁰ Several studies have noted an increased mortality when CAP patients have a delay in the initiation of appropriate antibiotic therapy, with most studies using an average of 6 hours since being first evaluated in the emergency room as the cutoff value.^{1,7,15,32,33} Renaud et al., in a study of 453 CAP patients, noted that the 28-day mortality was 11.7% for those with an obvious need for ICU care who were directly admitted to the ICU, which was significantly lower than the 23.4% mortality rate of those without obvious need for ICU care and had delayed admission.³⁴ Hraiech and associates divided CAP patients into those requiring MV within 72 hours of the onset of CAP and those with progressive respiratory failure requiring invasive MV 4 or more days after the onset of CAP.³⁵ There was a significant difference in mortality between the early respiratory failure group compared with the late respiratory failure group (28% vs. 51%, $P = 0.03$), suggesting that a delay in the identification of respiratory failure, transfer to ICU, or the development of progressive symptoms have deleterious effects on patient outcome.

In a study evaluating early cardiac events, including myocardial infarction and cardiac arrest in 55,276 patients, Carr and colleagues noted that 8% of cardiac arrest cases occurred in pneumonia patients; in this population, 62% of cardiac arrests occurred in patients admitted to the ICU, and only about 50% were on vasopressors or required MV.³⁶ Cardiac arrest occurred earlier in the ICU than in the ward (at a median of 18.9 vs. 28.4 hours) and was generally not a shockable rhythm (asystole or pulseless electrical activity). These findings suggest that patients with CAP in the hospital, or even the ICU, commonly have cardiac ischemia and that the event may be abrupt and without warning, potentially causing cardiorespiratory arrest. In another study, a restrictive red blood cell transfusion strategy (target hemoglobin level –7 to 9 g/dL in all patients, except those with acute myocardial infarcts or unstable angina) was associated with better outcomes for CAP patients.³⁷

When these findings are viewed together, they suggest some general principles. Mortality is more likely in CAP patients who have severe physiologic derangements, serious underlying illnesses, a delay in the initiation of appropriate antimicrobial therapy or MV, and the presence of atypical clinical features. This last factor suggests that an unusual clinical presentation (low fever, nondistinct respiratory symptoms) is associated with mortality, which may be the result of its reflecting an inadequate inflammatory response to infection and because it can also lead to a delay in the recognition of pneumonia and the institution of appropriate therapy.

■ PATHOGENESIS

Pneumonia results when host defenses are overwhelmed by an infectious pathogen. This may occur because the patient has an inadequate immune response, often as the result of underlying comorbid illness, anatomic abnormalities, acute illness-associated immune dysfunction, or therapy-induced dysfunction of the immune system. Pneumonia can also occur in patients who have an adequate immune system if the host defense system is overwhelmed by a large inoculum of microorganisms or if the patient encounters a particularly virulent organism to which he or she has no preexisting immunity or to which the patient has an inability to form an adequate acute immune response.^{38,39}

Microaspiration of infected oropharyngeal secretions is the most common mechanism associated with pneumonia. Other routes of entry include inhalation, which applies primarily to viruses, *Legionella pneumophila*, *Mycobacterium tuberculosis*, hematogenous dissemination from extrapulmonary sites of infection (right-sided endocarditis), and direct extension from contiguous sites of infection (such as liver abscess). Thus, previously healthy individuals develop infection with virulent pathogens such as viruses, *L. pneumophila*, *Mycoplasma pneumoniae*, *Chlamydia pneumoniae*, and *Streptococcus pneumoniae*. On the other hand, chronically ill patients can be infected by these organisms, as well as by organisms that commonly colonize patients but only cause infection when immune responses are inadequate. These organisms include enteric gram-negative bacteria (e.g., *Escherichia coli*, *Klebsiella pneumoniae*, *Pseudomonas aeruginosa*, *Acinetobacter* spp.) and fungi.

Studies that have evaluated the normal lung immune response to infection have shown that in most patients with unilateral CAP, the inflammatory response is limited to the site of infection.³⁹ In patients with localized pneumonia, tumor necrosis factor alpha (TNF α), interleukin (IL)-6, and IL-8 levels were increased in the pneumonic lung and generally not increased in the uninvolved lung or in the serum.^{40,41} On the other hand, in patients with severe pneumonia, the immune response is characterized by a “spillover” of the immune response into the systemic circulation, reflected by increases in the serum levels of TNF α and IL-6.⁴² It remains uncertain why localization does not occur in all individuals and why some patients develop diffuse lung injury (e.g., acute respiratory distress syndrome [ARDS]) or systemic sepsis as a consequence of pneumonia. These complications may result from an inability to develop a brisk lung immune response as a consequence of specific bacterial virulence factors, inadequate or delayed therapy, or genetic polymorphisms that affect the immune response.⁴³

Pneumonia-associated inflammation may also impact the long-term mortality and cognitive decline in CAP patients.⁴⁴⁻⁴⁶

■ CLINICAL FEATURES

Symptoms and Physical Findings

Patients with CAP and an intact immune system have a normal pulmonary response to infection and generally have respiratory symptoms such as cough, sputum production, and dyspnea, along with fever and other complaints. Cough is the most common finding and is present in up to 80% of all patients but is less common in those who are elderly, those with serious comorbidities, or patients coming from nursing homes.⁴⁷ Pleuritic chest pain is also common in patients with CAP, and in one study, its absence was also identified as a poor prognostic finding.⁴⁸ The elderly generally have fewer respiratory symptoms than younger individuals, and as mentioned, the absence of clear-cut respiratory symptoms and an afebrile status are themselves predictors of an increased risk of death.^{1,49} In elderly patients, pneumonia can have a nonrespiratory presentation, with symptoms of confusion, falling, failure to thrive, altered functional capacity, or deterioration in a pre-existing medical illness, such as congestive heart failure.^{47,50,51}

Physical findings of pneumonia include tachypnea, crackles, rhonchi, and signs of consolidation (egophony, bronchial breath sounds, dullness to percussion). Patients should also be evaluated for signs of pleural effusion. In addition, extrapulmonary findings should be sought to rule out metastatic infection (arthritis, endocarditis, meningitis) or to add to the suspicion of an “atypical” pathogen, such as *M. pneumoniae* or *C. pneumoniae*, which can lead to complications such as bullous myringitis, rash, pericarditis, hepatitis, hemolytic anemia, or meningoencephalitis. In the elderly, an elevation of respiratory rate can be the initial presenting sign of pneumonia, preceding other clinical findings by as much as 1 to 2 days.⁵² In fact, in one study, tachypnea was the most common finding in elderly patients with pneumonia, being present in over 60% of all patients and occurring more often in the elderly than in younger patients with pneumonia.⁴⁷

Radiographic Features

For most patients, CAP is defined by a combination of clinical symptoms and the presence of a new radiographic infiltrate, but not all patients with this illness will have this finding when first evaluated. Even when the radiograph is negative, if the patient has appropriate symptoms and focal physical findings, pneumonia may still be present. Although some studies have suggested that febrile and dehydrated patients can have a normal chest radiograph when first admitted with pneumonia, the idea of hydrating pneumonia is in the realm of “conventional wisdom” and anecdotal reports. The presence of alveolar densities (lobar or bronchopneumonic) has been associated with a high likelihood of a bacterial etiology, but it is extremely difficult to distinguish among specific pathogens using patterns of radiographic abnormalities.⁵³ Chest radiographs may have prognostic value in patients with severe pneumonia, multilobar infiltrates, or rapid progression of infiltrates serving as poor prognostic signs, helping to identify patients who require intensive care.^{1,7} Computed tomography (CT) scan of the chest generally has a higher sensitivity in diagnosing occult pneumonia with an initially negative chest radiograph.⁵⁴ Chest CT can also have value in the critically ill patient in situations when a noninfectious process is being considered or when complications such as pneumothorax, empyema, or abscess are suspected. CT can suggest certain alternative noninfectious diagnoses such as granulomatous vasculitis, acute eosinophilic pneumonia, and bronchiolitis obliterans with organizing pneumonia.

Lung ultrasound (LUS) denotes a new technique that has increasingly been adopted for diagnosing pleural and pulmonary diseases. Various patterns with B and M mode ultrasound techniques including “tissue sign,” “shred or fractal sign,” and “dynamic air bronchograms” are seen with pulmonary consolidation; whereas the “sinusoidal sign”

and “quad sign” are seen with even small pleural effusion.⁵⁵ In a prospective, multicenter study including 362 patients with suspected CAP, LUS was found to have a sensitivity of 93.4% and specificity of 97.7% compared with chest x-ray and chest CT.⁵⁶ In that study, the combination of LUS and auscultation decreased the negative likelihood ratio to 0.04 (95% confidence interval [CI]: 0.02-0.09), but the technique is operator dependent, and about 8% of pneumonic lesions are not visualized by LUS. The noninvasive nature of the test and rapidity with which it can be performed make this test another tool in the armamentarium for critical care physicians, and a recent meta-analysis of 10 studies with 1172 patients supports the use of LUS by skilled practitioners.⁵⁷

Severity Scoring in CAP

Although there is no uniformly accepted definition for SCAP, this term generally refers to any patient who is admitted to the ICU because of CAP. Most of these patients have severe sepsis or “respiratory failure,” which is defined by the presence of hypoxemia or hypercarbia, and not all such patients require MV. Some patients with CAP are treated in the ICU because the pneumonia has led to clinical instability of an underlying disease, but the pneumonia itself may not be severe. Bacteremia does not always correlate with more severe illness, and its presence alone is not always a predictor of a poor outcome, with most episodes of bacteremia being due to pneumococcus. However, in the elderly with pneumococcal pneumonia, bacteremia is present in one-fourth of patients with CAP and is often associated with azotemia and multilobar involvement.⁵⁸ When an infection such as pneumonia is complicated by severe sepsis or septic shock (not just bacteremia), the outcome is adversely affected, with increases in mortality, LOS, and costs for survivors.

One approach to evaluating CAP patients is to use a scoring system to define prognosis and predict the risk of death. The most widely used prognostic scoring systems are the Pneumonia Severity Index (PSI) and a modification of the British Thoracic Society (BTS) scoring system, the CURB-65 score. Other prediction rules, such as the American Thoracic Society (ATS)/Infectious Diseases Society of America (IDSA) criteria for SCAP, the Australian SMART-COP, the Japanese A-DROP scoring system, CAP-PIRO, and the Spanish CURXO-80 have also been developed for risk prognostication and to help with appropriate resource utilization.^{1,59-61}

The investigators in the Pneumonia Outcomes Research Team (PORT) study developed a mortality prediction rule that classifies all patients into one of five groups (PSI classes I to V), each with a different level of risk for death.⁶² Patients in classes IV and V have predicted mortality risks of 8.2% to 9.3% and 27% to 31.1%, respectively, whereas those in classes I and II have predicted mortality risks of 0.1% to 0.4% and 0.6% to 0.7%, respectively. To use this scoring system, patients have points calculated based on factors such as age, sex, the presence of comorbid medical disease, certain physical findings, and laboratory data.⁶² While the PORT scoring system has been shown to be accurate for predicting mortality and prognosis, it does not directly measure the severity of illness, and a poor correlation has been found between mortality and the need for ICU admission.⁶³ In a study evaluating patients in PORT class V, only about 20% needed ICU admission, and they had an overall mortality of 37%, compared with the 20% mortality of the PSI V patients who did not need the ICU.⁶⁴ In general, the PSI V patients who needed the ICU tended to get more of their points from acute illness, whereas those not needing the ICU tended to score points because of chronic disease factors. In addition, in young patients without comorbid illness, the pneumonia must be particularly severe to place the patient in a high mortality risk group, and certain vital sign thresholds must be exceeded to accumulate points toward a poor prognosis.

For the critical care physician, underestimating the severity of illness is a more serious concern, and the use of the CURB-65 approach, modified from the BTS rule, is a simple and accurate way to address this issue. CURB-65, an acronym for the clinical features used to assess

pneumonia severity and prognosis, assigns 1 point, on a five-point scale, to confusion, blood urea greater than 7 mmol/L, respiratory rate greater than or equal to 30 breaths/min, blood pressure of <90 mm Hg systolic or ≤60 mm Hg diastolic, and age greater than or equal to 65 years. In one study, when the score was 0 to 1, the mortality rate was 0%, whereas the mortality was more than 20% for a score of 3 or higher, and those with a score of 2 had a mortality of 8.3%.⁶⁵ The use of the CURB-65 rules may be a problem in the elderly, reflecting the altered clinical presentations of pneumonia in this population. Interestingly, although the rule was not optimal in an elderly population and did not work as well as it did in other populations, it had a higher sensitivity for predicting mortality than the PSI, which is derived from the PORT study. Some studies have compared the PSI and CURB-65 and found them to be similar for identifying low-risk populations; however, the CURB-65 may be better at identifying poor prognosis in those with severe illness, compared with the PSI.⁶⁶ An amended version of the CURB-65 that does not use the laboratory measurement of BUN, known as the CRB-65, has also been found to be similarly accurate.⁶⁷ In another study comparing the performance of PSI and CURB-65 risk scores, the discriminatory power for 30-day mortality, using both PSI and CURB-65, was lower in HCAP than in CAP patients.⁶⁸

Other prognostic scoring systems have been developed to define the presence of severe pneumonia. Espana and associates estimated the need for ICU admission by the presence of one of two major criteria: arterial pH < 7.30 or systolic BP < 90 mm Hg.⁶¹ In the absence of these criteria, SCAP can also be identified by the presence of two of six minor criteria, including confusion, BUN > 30 mg/dL, respiratory rate > 30/min, PaO₂/FiO₂ ratio < 250, multilobar infiltrates, and an age of at least 80 years. When these criteria were met, the tool was 92% sensitive for identifying those with SCAP and was more accurate than the PSI or CURB-65 criteria, although not quite as specific as the CURB-65 rule.⁶¹ Using this approach, some criteria (acidosis and systolic hypotension) are weighted more heavily than others, which contrasts with some of the other approaches to define SCAP.

A different method than assessing risk for death is to use scoring systems to define the need for ICU interventions such as intensive respiratory and vasopressor support (IRVS). The SMART-COP tool was developed to predict the need for IRVS.⁶⁰ Using a multivariate model, there were eight clinical features associated with the need for IRVS: systolic blood pressure < 90 mm Hg, multilobar infiltrates, albumin < 3.5 g/dL, respiratory rate elevation (>25 breaths/min for those aged <50 years, and >30 breaths/min for those aged >50 years), tachycardia (>125 beats/min), confusion, low oxygen (<70 mm Hg if aged <50 years or <60 mm Hg if aged >50 years), and arterial pH < 7.35. Abnormalities in systolic blood pressure, oxygenation, and arterial pH each received 2 points, while the five other criteria received 1 point each, and with this system, the need for IRVS was predicted by a SMART-COP score of at least 3 points. Using this cutoff, the sensitivity for need for IRVS was 92.3% and the specificity was 62.3%, with positive and negative predictive values of 22% and 98.6%, respectively. The PSI and CURB-65 did not perform as well overall for predicting the need for IRVS.

The most recent ATS/IDSA guidelines for CAP suggested that ICU care be considered if the patient has one of two major criteria (need for MV or septic shock with the need for vasopressors) or three of nine minor criteria.¹ The minor criteria include respiratory rate > 30 breaths/min, PaO₂/FiO₂ ratio < 250, multilobar infiltrates, confusion/disorientation, uremia (BUN level > 20 mg/dL), leukopenia (white blood cell count < 4000 cells/mm³), thrombocytopenia (platelet count < 100,000 cells/mm³), hypothermia (core temperature < 36°C), and hypotension requiring aggressive fluid resuscitation. Other factors to consider in the decision-making process are hypoglycemia (in a non-diabetic patient), hyponatremia, acute alcohol intoxication, cirrhosis, asplenia, and unexplained metabolic acidosis. The use of these minor criteria alone requires validation, with one study showing that patients who met only minor criteria for ICU admission did not have an increase in mortality, while in another study, the use of four minor criteria instead of three improved the accuracy in defining the need for

ICU admission.^{69,70} Phua and colleagues showed that the ATS minor criteria had greater discriminatory power in the prediction of severity, ICU admission, and mortality than the PSI and CURB.⁷¹ Brown and associates noted that both the positive and negative predictive values of the minor criteria exceeded 80% if four criteria were used to define the need for ICU admission rather than just three criteria.⁷⁰ In a recent study, investigators simplified the ATS/IDSA criteria by excluding variables that occurred in <5% of cases, including leukopenia, thrombocytopenia, and hypothermia and noted similar predictive values for mortality and ICU admission as compared with those for the original ATS/IDSA criteria.⁷² In the same study, the addition of another variable, acidosis (pH < 7.35), improved the prediction for mortality and for ICU admission.

Rello and associates evaluated the “CAP-PIRO score” calculated within 24 hours of ICU admission.⁷³ In this study, 1 point was assigned for each variable: comorbidities (COPD, immunocompromised), age greater than 70 years, multilobar opacities on chest radiograph, shock, severe hypoxemia, acute renal failure, bacteremia, and ARDS. Patients were stratified into four levels of risk: (1) low, 0 to 2 points; (2) mild, 3 points; (3) high, 4 points; and (4) very high, 5 to 8 points. The PIRO score performed well as a 28-day mortality prediction tool in patients with CAP requiring ICU admission, with a better performance than APACHE II and the ATS/IDSA criteria.

The Risk of Early Admission to ICU (REA-ICU) index was derived from a dataset of nearly 5000 patients and is helpful as a tool on admission to identify patients who had no obvious indication for ICU management but subsequently required ICU care. It categorizes individuals into four risk groups based on 11 criteria independently associated with ICU admission: male gender, age younger than 80 years, comorbid conditions, respiratory rate of 30 breaths/min or higher, heart rate of 125 beats/min or higher, multilobar infiltrate or pleural effusion, white blood cell count less than 3 or 20,000/L or above, hypoxemia (oxygen saturation < 90% or arterial partial pressure of oxygen [PaO₂] < 60 mm Hg), BUN of 11 mmol/L or higher, pH less than 7.35, and sodium less than 130 mEq/L.⁷⁴ The mortality and likelihood of needing ICU care increased with each successive risk group, with the highest in class IV with a score ≥ 9. In a recent validation study including 850 CAP patients who had no obvious need for ICU care on admission, the REA-ICU index performed better than PSI but was similar to other tools (such as SMART-COP, CURXO-80, the 2007 ATS/IDSA minor severity criteria, and CURB-65) at defining the need for early ICU admission.⁷⁵ The need for sensitive criteria to define severe illness in CAP patients is important, since the benefit seems most certain if patients are admitted to the ICU early during the course of severe illness.

Role of Biomarkers in SCAP

The measurement of serum levels of biomarkers, such as C-reactive protein, midregional proadrenomedullin, midregional proatrial natriuretic peptide (MR-proANP), proarginine-vasopressin (Copeptin), proendothelin-1, or PCT, may be valuable in guiding the management of antibiotics for CAP. PCT is an acute phase reactant synthesized in the liver in response to bacterial, but not viral, infection. Studies on CAP have documented that serial measurement of the levels of PCT can guide the duration of antibiotic therapy, allowing cessation of therapy once levels fall and leading to a marked reduction in the duration of therapy compared with clinical judgment.^{5,76} In patients with SCAP, the measurement of initial and serial levels can help to identify those with a poor prognosis, and a low PCT value may distinguish which patients in PSI classes IV and V might be safely managed out of the ICU.⁷⁷ Kruger et al. reported that nonsurvivors had significantly higher median PCT levels on admission than survivors (0.88 vs. 0.13 ng/mL; $P = 0.0001$).⁷⁸ Low PCT accurately predicted patients at very low risk of death, even in those patients in a high prognostic scoring category by CURB-65 evaluation. Given its high negative predictive potential (98.9% with a PCT level of <0.228 ng/mL), patients with low initial PCT might be safely treated out of the ICU.⁷⁸ Huang

et al. found that 23.1% (126/546) of high-risk patients defined by PSI had low PCT levels on the first hospital day, and this subgroup had very low mortality, similar to low-risk patients.⁷⁹

In a prospective study of 685 CAP patients, Ramirez and associates evaluated the relationship between biomarkers and ICU admission.⁸⁰ Inflammatory biomarkers helped identify patients needing intensive care monitoring, including those requiring delayed ICU admission. No patient with ≥ 3 ATS minor severity criteria and PCT levels below the cutoff (0.35 ng/mL) needed ICU admission compared with 14 (23%) with levels above the cutoff ($P = 0.032$).⁸⁰ In another study, the authors compared the levels of three biomarkers—N-terminal pro-B-type natriuretic peptide (NT-proBNP), MR-proANP, and B-type natriuretic peptide (BNP)—with the PSI and CURB-65 scores for predicting short- and long-term mortality.⁸¹ The levels of NT-proBNP, MR-proANP, and BNP increased with the severity of pneumonia, and patients who died had higher levels of all three biomarkers. A combined assessment using categorical PSI score and NT-proBNP levels seemed beneficial over a single-marker approach for short- and long-term risk stratification. In a recent meta-analysis of seven studies including 1075 patients, using a PCT-based regimen in patients with severe sepsis or septic shock, the 28-day mortality was not different between the PCT-based regimen and standard treatment groups, but the PCT-guided group had a shorter duration of antimicrobial therapy.⁸² Using a PCT-based strategy led to more de-escalation and a shorter duration of antibiotic therapy, with no adverse effect on mortality.

Using biomarkers to adjudicate severity is best done in conjunction with clinical, microbiological, and pathologic data. A combined approach including severity scores and biomarkers can aid clinicians in assessing the severity of the illness and the need for the use of antibiotics, and serial measurements can be used to assess the treatment response. However, PCT or other biomarkers are not specific for pneumonia itself and can be elevated in other infectious or inflammatory conditions and, thus, should be interpreted with caution in patients with cardiac and renal failure.

ETIOLOGIC PATHOGENS

Even with extensive diagnostic testing, an etiologic agent is identified in only about half of all patients with CAP, pointing out the limited value of diagnostic testing and the possibility that we do not know all the organisms that can cause CAP.^{1,83} In the past 4 decades, a variety of new pathogens for this illness have been identified, including *L. pneumophila*, *C. pneumoniae*, Middle East respiratory syndrome coronavirus (MERS-CoV), avian-origin influenza A (H7N9), novel H1N1, H3N2 influenza, and hantavirus. In addition, antibiotic-resistant variants of common pathogens, such as *S. pneumoniae*, have become increasingly common. However, recent data show a decreased ICU mortality in pneumococcal CAP between 2000 and 2013, which likely reflects appropriate identification of SCAP, early antibiotic prescription, and increased use of combination therapy.⁸⁴

The likely pathogens for infection vary depending on patient risk factors for specific microorganisms and the presence of certain comorbid illnesses, but for all patient groups, including those with SCAP, pneumococcus is the most common pathogen.^{1,85} The incidence of antibiotic-resistant pneumococci has increased in recent years, and up to 40% of these organisms can have reduced sensitivity to penicillin or other antibiotics, although the clinical relevance of *in vitro* resistance is still uncertain.^{1,86,87} Although *S. pneumoniae* is the most common organism causing CAP, the frequency of pneumococcal pneumonia has declined, probably due to effective vaccination practices and a decreased incidence of smoking in adults.⁸⁸ Identified risk factors for drug-resistant *S. pneumoniae* (DRSP) include beta-lactam therapy in the past 3 months, alcoholism, age older than 65 years, immune suppression, multiple medical comorbidities, and contact with a child in daycare.^{1,89,90} Other common infecting organisms in those with SCAP include viruses (e.g., influenza, respiratory syncytial virus, and the coronavirus illness of severe acute respiratory syndrome [SARS]), *L.*

pneumophila, *M. pneumoniae*, *M. tuberculosis*, and *Haemophilus influenzae* (especially in smokers). In the setting of severe pneumonia, patients can be infected with *S. aureus* (including methicillin-resistant forms, or MRSA) or enteric gram-negatives and, rarely, anaerobes. In the elderly, including those with aspiration pneumonia, HCAP and, in those with underlying cardiopulmonary disease, enteric gram-negative organisms are often seen.

Although aspiration has often been considered a risk factor for anaerobic infection, studies of SCAP in elderly patients with aspiration risk factors have suggested that this population is very likely to have gram-negative infection.^{91,92} Risk factors for gram-negative organisms causing CAP are probable aspiration, previous hospital admission within 30 days of admission, previous antibiotic use within 30 days of admission, the presence of pulmonary comorbidity, smoking, and hyponatremia.^{93,94} Falguera and associates, in a study of 3272 episodes of CAP, found that 2% were caused by enteric gram-negatives (most commonly *P. aeruginosa*), and the risk factors for these organisms were COPD, current use of corticosteroids, prior antibiotic therapy, tachypnea > 30 breaths/min, and septic shock on admission.⁹⁵ Patients with these organisms needed ICU care more often and had a higher mortality and longer LOS than those without these pathogens present.

Primary pulmonary infection with atypical pathogens has been reported for patients with SCAP for many years. In fact, in one ICU in Spain, atypical pathogens were present in almost 25% of all patients, but the responsible organism varied over time. *Legionella* was the most common atypical pathogen leading to SCAP in 14% of patients during one time period, but in the same hospital a decade later, it was seen in only 2% of patients, having been replaced by *Mycoplasma* and *Chlamydia* infection, which were found in 17% of patients compared with only 6% a decade earlier.¹⁵ Several studies have shown that even if bacterial pathogens lead to CAP, they can be accompanied by atypical pathogens in the form of mixed infection.^{96,97} Atypical pathogens can include *C. pneumoniae*, *M. pneumoniae*, and *L. pneumophila*, and some studies have shown that these infections are common in patients of all ages, not just young and healthy individuals; these organisms have even been reported among the elderly in nursing homes.^{1,96,98} When mixed infection is present, it may lead to a more complex course and a longer LOS than if a single pathogen is present, which may explain the increasing numbers of studies that show a reduction in CAP mortality, including those in the ICU, when initial therapy provides coverage for these organisms, compared with regimens that do not.^{99,100} Interestingly, multiple retrospective studies of pneumococcal bacteremia have shown a reduced mortality when dual therapy (usually involving a macrolide) rather than monotherapy is used, raising the possibility that even these patients have mixed infection with atypical pathogens.^{101,102} The frequency of atypical pathogens can be as high as 60%, with as many as 40% of all CAP patients having mixed infection.⁹⁷ These high incidence rates have been derived by serologic testing, which is of uncertain accuracy. Atypical organism pneumonia may not be a constant phenomenon, and the frequency of infection may vary over the course of time and with geography.

In the past, *S. aureus* was an uncommon cause of CAP, but it was capable of leading to severe pneumonia. In the past several years, a community-acquired strain of MRSA (CA-MRSA) has emerged as a cause of SCAP, particularly in patients without a history of previous hospitalization or chronic illness, often as a complication of influenza infection.^{1,103,104} The organism can lead to a severe, bilateral, necrotizing pneumonia, often related to toxin production by the organism. This organism is distinct from the nosocomial strain of MRSA and is clonal in origin, usually due to the USA 300 strain.

Risk Factors for Specific Pathogens

Table 74-3 summarizes the common pathogens causing CAP in hospitalized patients, including those admitted to the ICU. The classification is based on the presence of clinical risk factors for specific pathogens, referred to as “modifying factors.” The modifying factors for DRSP are age older than 65 years, beta-lactam therapy within the

TABLE 74-3

Common Pathogens Causing Community-Acquired Pneumonia

INPATIENT, WITH NO CARDIOPULMONARY DISEASE OR MODIFYING FACTORS

Streptococcus pneumoniae, *Haemophilus influenzae*, *Mycoplasma pneumoniae*, *Chlamydia pneumoniae*, mixed infection (bacteria plus atypical pathogen), viruses (including influenza), *Legionella* spp., and others (*Mycobacterium tuberculosis*, endemic fungi, *Pneumocystis jirovecii*)

INPATIENT, WITH CARDIOPULMONARY DISEASE AND/OR MODIFYING FACTORS

All of the above, but drug-resistant *S. pneumoniae* (DRSP) and enteric gram-negative organisms are more of a concern

SEVERE COMMUNITY-ACQUIRED PNEUMONIA, WITH NO RISKS FOR *PSEUDOMONAS AERUGINOSA*

S. pneumoniae (including DRSP), *Legionella* spp., *H. influenzae*, enteric gram-negative bacilli, *Staphylococcus aureus* (including methicillin-resistant *S. aureus*), *M. pneumoniae*, respiratory viruses (including influenza), others (*C. pneumoniae*, *M. tuberculosis*, endemic fungi)

SEVERE CAP, WITH RISKS FOR *P. AERUGINOSA*

All of the pathogens above plus *P. aeruginosa*

past 3 months, alcoholism, immune-suppressive illness (including therapy with corticosteroids), multiple medical comorbidities, and exposure to a child in daycare. For the patient with HCAP, infection by resistant gram-negatives and MRSA can occur, particularly if the patient has multiple risk factors, in addition to nursing home residence. These risk factors include severe illness, poor functional status, immune suppression, recent antibiotic therapy, and recent hospitalization in the past 3 months.¹⁰⁵ In predicting the likely etiologic pathogens for those admitted to the ICU, patients are divided into a population at risk for *Pseudomonas* infection and a population in whom this organism is unlikely to be present. The risk factors for *P. aeruginosa* infection are structural lung disease (bronchiectasis), corticosteroid therapy (>10 mg prednisone/day), broad-spectrum antibiotic therapy for more than 7 days in the past month, and malnutrition.¹ In a study of 935 patients admitted with CAP or HCAP, the authors evaluated risk factors for infection with MDR pathogens according to the ATS/IDSA 2005 HCAP guidelines.¹⁰⁶ Patients with at least one risk factor for MDR pathogens had more severe pneumonia on admission and a higher prevalence of severe sepsis compared with those without (45% vs. 29%, $P < 0.001$; 31% vs. 21%, $P = 0.001$), and of all the risk factors, hospitalization in the preceding 90 days (OR 4.87) and residence in a nursing home (OR 3.55) were independent predictors of infection with a resistant pathogen and mortality. Table 74-4 shows that certain clinical conditions are associated with specific pathogens, and these associations should be considered in all patients when obtaining a history.¹

Although a variety of radiographic patterns can be seen in pneumonia, specific findings generally cannot be used to predict the microbial etiology in CAP, but there are certain patterns to keep in mind. Focal consolidation can be seen in infections caused by pneumococcus, *Klebsiella* sp., aspiration (especially if in the lower lobes or other dependent segments), *S. aureus*, *H. influenzae*, *M. pneumoniae*, and *C. pneumoniae*. Interstitial infiltrates suggest viral pneumonia as well as infection due to *M. pneumoniae*, *C. pneumoniae*, *Chlamydia psittaci*, and *Pneumocystis jirovecii*. Lymphadenopathy with an interstitial pattern should raise concerns about anthrax, *Francisella tularensis*, and *C. psittaci*, whereas adenopathy can be seen with focal infiltrates in tuberculosis, fungal pneumonia, anthrax, and bacterial pneumonia. Cavitation can be the result of an aspiration lung abscess, infection with *S. aureus* or aerobic gram-negatives (including *P. aeruginosa*), tuberculosis, fungal infection (*Aspergillus*), nocardiosis, and actinomycosis.

TABLE 74-4 Clinical Associations with Specific Pathogens

| CONDITION | COMMONLY ENCOUNTERED PATHOGENS |
|--|--|
| Alcoholism | <i>Streptococcus pneumoniae</i> (including penicillin-resistant), anaerobes, gram-negative bacilli (possibly <i>Klebsiella pneumoniae</i>), tuberculosis |
| Chronic obstructive pulmonary disease/ current or former smoker | <i>S. pneumoniae</i> , <i>Haemophilus influenzae</i> , <i>Moraxella catarrhalis</i> |
| Residence in nursing home | <i>S. pneumoniae</i> , gram-negative bacilli, <i>H. influenzae</i> , <i>Staphylococcus aureus</i> , <i>Chlamydia pneumoniae</i> ; consider <i>M. tuberculosis</i> . Consider anaerobes, but these are less common. |
| Poor dental hygiene | Anaerobes |
| Bat exposure | <i>Histoplasma capsulatum</i> |
| Bird exposure | <i>Chlamydia psittaci</i> , <i>Cryptococcus neoformans</i> , <i>H. capsulatum</i> |
| Rabbit exposure | <i>Francisella tularensis</i> |
| Travel to southwestern United States | <i>Coccidioidomycosis</i> ; hantavirus in selected areas |
| Exposure to farm animals or parturient cats | <i>Coxiella burnetii</i> (Q fever) |
| Post-influenza pneumonia | <i>S. pneumoniae</i> , <i>S. aureus</i> (including the community-acquired strain of methicillin-resistant <i>S. aureus</i>), <i>H. influenzae</i> |
| Structural disease of the lung (e.g., bronchiectasis, cystic fibrosis) | <i>Pseudomonas aeruginosa</i> , <i>Pseudomonas cepacia</i> , or <i>S. aureus</i> |
| Sickle cell disease, asplenia | Pneumococcus, <i>H. influenzae</i> |
| Suspected bioterrorism | Anthrax, tularemia, plague |
| Travel to Asia | Severe acute respiratory syndrome, tuberculosis, melioidosis |

Features of Specific Pathogens

Streptococcus pneumoniae

The most common pathogen for CAP, this organism is a gram-positive, lancet-shaped diplococcus, of which there are 84 different serotypes, each with a distinct antigenic polysaccharide capsule. Eighty-five percent of all infections are caused by one of 23 serotypes, which are included in a polysaccharide vaccine. Infection is most common in the winter and early spring, which may be related to the finding that up to 70% of patients have a preceding viral illness. The organism spreads from person to person and commonly colonizes the oropharynx before it leads to pneumonia. Pneumonia develops when the colonizing organisms are aspirated into a lung that is unable to contain the aspirated inoculum. Bacteremia is present in up to 20% of hospitalized patients, and extrapulmonary complications include meningitis, empyema, arthritis, endocarditis, and brain abscess. The burden of pneumococcal disease is often underestimated, since most studies report the incidence of bacteremic or invasive pneumococcal disease. Said and colleagues, in a systematic review and meta-analysis, estimated the proportion of CAP attributable to pneumococcus as 27.3% and, using urine antigen testing, helped diagnose an additional 11.4% of pneumococcal CAP beyond conventional techniques.¹⁰⁷ In that study, 24.8% of all cases were bacteremic, and it was more common among those with severe illness, no prior antibiotic use, and a positive human immunodeficiency virus (HIV) status. As mentioned elsewhere, there is also a trend toward improved survival with severe

pneumococcal CAP in the ICU due to improved antibiotic prescription practices and a decrease in smoking in recent years.⁸⁴

Since the mid-1990s, antibiotic resistance among pneumococci has become increasingly common, and penicillin resistance, along with resistance to other common antibiotics (macrolides, trimethoprim/sulfamethoxazole, selected cephalosporins), is present in over 40% of these organisms.^{1,86-90} Fortunately, most penicillin resistance is of the “intermediate” type (penicillin minimal inhibitory concentration [MIC] of 0.1 to 1.0 mg/L) and not of the high-level type (penicillin MIC of 2.0 or more). Although the clinical impact of *in vitro* resistance is uncertain, one large database has data showing that only organisms with a penicillin MIC of more than 4 mg/L can lead to an increased risk of death.⁸⁶ Recently, the definitions of resistance have been changed for non-meningeal infection, with sensitive being defined by a penicillin MIC ≤ 2 mg/L, intermediate as an MIC of 4 mg/L, and resistant as an MIC ≥ 8 mg/L.¹⁰⁸ While the clinical impact of resistance on outcomes such as mortality was hard to show using older definitions, with the new definitions of resistance, very few pathogens will be defined as resistant, but those that are may affect the outcome. In a recent study including 118 patients using the new definition for resistance, there was no difference in 30-day mortality between the penicillin-susceptible and -resistant groups.¹⁰⁹ The penicillin-resistant group had a higher frequency of having received antibiotics within the past 2 weeks, but interestingly, it was the susceptible group who had a higher frequency of worse initial presentation such as ICU admissions and bacteremia. In this cohort, both groups received equally broad spectrum antibiotics such as extended-spectrum cephalosporins, vancomycin, and a carbapenem.

The relationship between prior antibiotic use and subsequent pneumococcal resistance is well known, and prior therapy with macrolides, beta-lactams, and quinolones has been identified as a predisposing factor for subsequent resistance to the same class of antibiotic.^{89,110-112} The risk was no lower for therapy in the past 6 months compared with therapy in the past 1 month.¹¹² Other studies have shown that quinolone therapy can predispose to subsequent pneumococcal resistance to this class of antibiotics.^{110,111} In another study of patients with pneumococcal bacteremia, pneumococcal resistance to beta-lactams (penicillins and cephalosporins), macrolides, and quinolones was more likely if the patient had received the same agent in the past 3 months.¹¹⁰ Although some studies have shown that discordant therapy of drug-resistant pneumococcus can be a risk factor for mortality, in one study, discordant therapy was less likely if patients were treated with ceftriaxone or cefotaxime compared with other therapies.¹¹³ Thus, in clinical practice, resistance is not likely to affect the outcome, since current guidelines for SCAP recommend the use of these effective agents as empiric therapy. Macrolide-resistant pneumococci have also been described and can be either low- or high-level resistant, depending on whether the mechanism of resistance is efflux or ribosomal alteration, respectively. Although high-level resistance may be clinically relevant, this is generally not an issue in the management of ICU CAP, since all patients who receive macrolide therapy do so in combination with a highly active beta-lactam that is effective against pneumococcus, even if macrolide resistance is present.

Legionella pneumophila

This small, weakly staining, gram-negative bacillus was first characterized after an epidemic in 1976 and can occur either sporadically or in epidemic form. Although multiple serogroups of the species *L. pneumophila* have been described, and these account for 90% of all cases of legionnaires' disease, serogroup 1 is responsible for most cases. The other species that commonly causes human illness is *Legionella micdadei*, which is waterborne and can emanate from air-conditioning equipment, drinking water, lakes and river banks, water faucets, and shower heads.¹¹⁴ Infection is generally caused by inhalation of an infected aerosol generated by a contaminated water source. When a water system becomes infected in an institution, endemic outbreaks may occur. In its sporadic form, *Legionella* may account for 7% to 15% of all cases of CAP, being a particular concern in patients with

severe forms of illness.^{1,15,114} Recent studies show an increase in the reported cases of *Legionella*, especially in big cities like New York and a higher incidence in diabetes patients and those from poor neighborhoods.¹¹⁵

The classic *Legionella* syndrome is characterized by high fever, chills, headache, myalgias, and leukocytosis.¹¹⁴ The diagnosis is also suggested by the presence of pneumonia with preceding diarrhea, along with mental confusion, hyponatremia, relative bradycardia, and liver function abnormalities, but this syndrome is usually not present. Symptoms are rapidly progressive, and the patient may appear to be quite toxic. This classic syndrome is not always present, so this diagnosis should always be considered in patients admitted to the ICU with CAP and in those with rapidly progressive radiographic abnormalities. To establish this diagnosis serologically, it is necessary to collect both acute and convalescent titers. The urinary antigen test (UAT) is the single most accurate acute diagnostic test for *Legionella* but is specific only for serogroup 1 infection. However, it does not detect other types of *Legionella*, so a negative finding cannot rule out this infection. In recent years, most cases have been diagnosed with urinary antigen, and there has been less reliance on serology and culture.¹¹⁶ With this increased reliance on UAT, the case fatality rate of *Legionella* has fallen, possibly reflecting diagnosis of less severe illness than in the past.¹¹⁶

Staphylococcus aureus

Staphylococcus aureus can lead to severe forms of CAP, which can be necrotizing, develop cavitory pneumonia, and have hematogenous dissemination to multiple sites in the body. The organism can also seed the lung hematogenously from valvular vegetations in patients with right-sided endocarditis or from septic venous thrombophlebitis (from central venous catheter or jugular vein infection). When a patient develops postinfluenza pneumonia, *S. aureus* can lead to secondary bacterial infection and, in the United States, CA-MRSA have emerged, primarily in skin and soft tissue infections, but also as a cause of SCAP. CA-MRSA is a clonal disease, emanating from the USA 300 clone of *S. aureus*, and is clinically and bacteriologically different from the strains of MRSA that cause nosocomial pneumonia.¹⁰³ In addition, it can infect previously healthy individuals, and the classic clinical presentation of this pathogen causing CAP is as a complication of a preceding viral or influenza infection.

This illness is characterized by a severe, bilateral, necrotizing pneumonia, which may be related to staphylococcal virulence factors such as Panton-Valentine leukocidin (PVL). In a prospective study of 627 patients from 12 emergency departments across the United States during two influenza seasons, the authors isolated CA-MRSA from 2.4% of all patients and 5% of patients admitted to the ICU; the mortality rate was 14%, and all isolates were of the USA 300 strain.¹¹⁷ CA-MRSA patients had severe infection with multiple infiltrates or cavities on chest imaging, were intubated or required vasopressors, and, compared with other patients, were more likely to develop illness after nursing home admission in the previous year or after close contact in the previous month with someone with a skin infection. Since the pathogenesis of pneumonia due to this organism may be related to toxin production by the bacteria, therapy may need to involve both an antibacterial agent and an antitoxin-producing agent.¹⁰⁴ Sicot and associates, in a study of 133 patients with PVL-positive CAP, found similar mortality rates between patients who had MRSA and methicillin-susceptible *S. aureus*. However, treatment with antibiotics with antitoxin effects (clindamycin, rifampin, and linezolid) was associated with a reduced mortality compared with those who did not receive antitoxin therapy (6.1% vs. 52.3%, $P < 0.001$), although only about one-third of patients received this therapy.¹¹⁸ The frequency of this illness is still relatively low, but it does occur sporadically, with certain geographic areas having a high frequency, especially during influenza season.

Other Organisms

The incidence of viral pneumonia is difficult to define, but one careful study of over 300 nonimmunocompromised CAP patients

looked for viral pneumonia by paired serologies and found that 18% had viral pneumonia, with about half being pure viral infection and the others being mixed with bacterial pneumonia.¹¹⁹ Influenza (A more than B), parainfluenza, and adenovirus were the most commonly identified viral agents. Viral illnesses that can lead to respiratory failure, in addition to influenza, include respiratory syncytial virus (which can affect the elderly), varicella (a particular concern in pregnant females with chickenpox), and hantavirus (endemic in the Four Corners area of New Mexico).¹²⁰ In a recent study in patients with severe pneumonia using polymerase chain reaction (PCR) techniques, the authors found viral infection to be common: 36.4% ($n = 72$) had positive viral markers, and 9.1% ($n = 18$) had bacterial and viral co-infections.¹²¹

It is important to always consider the diagnosis of tuberculosis in patients with SCAP and fungal infections with coccidioidomycosis and histoplasmosis in endemic areas, especially in HIV-infected persons. Several rickettsiae can also cause CAP, including Q fever (*Coxiella burnetii*), which occurs worldwide, Rocky Mountain spotted fever (RMSF), and scrub typhus (*Rickettsia tsutsugamushi*) in Asia and Australia. Transmission typically involves an intermediate vector, often ticks (Q fever, RMSF) or mites (scrub typhus), but also sheep, cows, and contaminated milk (Q fever). These infections have a variable incubation period, ranging from days to a few weeks, and are characterized by a febrile syndrome that may have a pneumonic component and a maculopapular rash (Q fever and RMSF).

Influenza. Influenza should always be considered during epidemic times and can lead to primary viral pneumonia or to secondary bacterial infection with pneumococcus, *S. aureus*, or *H. influenzae*. In April 2009, an outbreak of H1N1 influenza infected approximately 61 million people worldwide, with as many as 13,000 deaths. H1N1 influenza, in contrast to seasonal flu, affected younger people more than the elderly, and high-risk populations included pregnant women and those with obesity.¹²² In one series, 12% of all hospitalized patients with H1N1 infection were administered MV, and 6% of hospitalized patients died.¹²³ Antiviral therapy with zanamivir and oseltamivir may reduce the severity of illness, particularly if given early, and the role of corticosteroids for patients with severe illness is controversial.^{122,124} The frequency of documented bacterial pneumonia complicating this illness varies from <5% to >25% of patients with radiographic pneumonia. Muscedere and associates evaluated the risk of coexistent or secondarily acquired bacterial respiratory tract or bloodstream-positive cultures in 681 patients with 2009 influenza A (H1N1) infection.¹²⁵ In that study, 38% of patients had at least a positive blood or respiratory culture during their ICU stay, although almost all the patients received antibiotics; patients with any positive cultures had higher morbidity, with more days on the ventilator, longer ICU and hospital LOS, and higher hospital mortality compared with those with negative cultures. Recently, during the spring of 2013, infection with novel avian-origin influenza A (H7N9) emerged in China and was related to exposure to live animals, including chickens (82%).¹²⁶ It was linked with a high incidence of respiratory failure and ICU admission, especially in those with comorbid conditions, and mortality ranged from 27% to 34% among ICU patients.^{126,127}

Severe Acute Respiratory Syndrome. In late 2003, a respiratory viral infection, caused by a coronavirus, emerged in parts of Asia and was termed SARS. The illness affected people from a variety of endemic areas in Asia but was seen in North America when an outbreak occurred in Toronto, Canada. Importantly, worldwide, as many as 20% of affected patients were health care workers, particularly those caring for patients admitted to the ICU. Transmission risk was greatest during emergent intubation, and was also possible during noninvasive ventilation, making this latter modality of therapy contraindicated if SARS is suspected.¹²⁸ Infection control may be quite effective in preventing the spread of SARS to health care workers and includes the careful handling of respiratory secretions, ventilator circuits, the use of N-95 respirator masks, and careful gowning and gloving.¹²⁹ Even more elaborate infection control measures, including personal air exchange units, are needed for health care workers involved in high-risk procedures such

as intubation. The mortality rate for ICU-admitted SARS patients was over 30%, and when patients died, it was generally from multiple system organ failure and sepsis. There is no specific therapy, but anecdotal reports have suggested a benefit of the use of pulse doses of corticosteroids and ribavirin.

Middle East Respiratory Syndrome Coronavirus. A new coronavirus outbreak, subsequently named *MERS-CoV*, started in September 2012 in the Arabian Peninsula.¹³⁰ Patients presented with severe acute pneumonia, with hypoxemic respiratory and renal failure. It can occur sporadically in the community, as well as from health-care-associated human-to-human transmission.¹³¹ The infection was associated with a very high fatality rate of up to 60%, especially in patients with medical comorbidities, and the majority of patients required invasive respiratory support and had extrapulmonary manifestations, mainly kidney failure.¹³² The roles of steroids, oseltamivir, ribavirin, and interferon for treatment are uncertain.

Bioterrorism Considerations

Certain airborne pathogens can cause pneumonia as the result of deliberate dissemination by the aerosol route, in the form of a biologic weapon, and present a clinical syndrome of CAP. The pathogens that are most likely to be used in this fashion and that can lead to severe pulmonary infection are *Bacillus anthracis* (anthrax), *Yersinia pestis* (plague), and *F. tularensis* (tularemia).¹³³⁻¹³⁷ The Centers for Disease Control and Prevention has classified these agents as category A pathogens because of their high mortality rate and their potential impact on public health.¹³³ Other pneumonic pathogens could also serve as agents of biologic warfare but are potentially less serious and are classed in category B and include *C. burnetii* and *Brucella* sp. Certain emerging pathogens are category C agents and are not widely available as weapons but have the potential for high morbidity and mortality, including hantavirus and MDR tuberculosis. Some agents of bioterrorism can be spread via the aerosol route but do not generally present as pneumonia and include smallpox and viral hemorrhagic fevers (Ebola, Marburg).

DIAGNOSTIC EVALUATION

As discussed, the diagnosis of CAP is suggested by the patient's history and physical examination and confirmed by chest radiograph. The history may suggest certain pathogens on the basis of epidemiologic considerations (Table 74-4), but the clinical features and chest radiograph cannot give an exact etiologic diagnosis. In patients with SCAP, diagnostic testing is performed to define the presence of pneumonia, the severity of illness and its complications, and the etiologic pathogen. Although defining a specific etiologic diagnosis of CAP allows for focused antibiotic therapy, most patients do not have a specific pathogen identified, and many who do have this diagnosis made days or weeks later, as the results of cultures or serologic testing become available. An etiologic diagnosis is best established if blood or pleural fluid cultures identify a pathogen, if bronchoscopic techniques demonstrate an organism in high concentrations, or if serologic testing confirms a fourfold rise in titers to specific pathogens (comparing acute and convalescent samples collected weeks apart).

For ICU-admitted patients, after a chest radiograph defines the presence of pneumonia, testing should include an assessment of oxygenation (pulse oximetry or blood gas, the latter if retention of carbon dioxide is suspected), routine admission blood work, and two sets of blood cultures¹ (Table 74-5). Although blood cultures are positive in only 10% to 20% of CAP patients, they can be used to define a specific diagnosis and to define the presence of drug-resistant pneumococci.^{1,86} Blood cultures are not routine for all admitted patients but should be performed in those with severe illness, especially if the patient has not received antibiotics prior to admission, since the incidence of a true-positive result is high in this population.¹³⁸ If the patient has a pleural effusion, this should be tapped and the fluid sent for culture and biochemical analysis.

Sputum culture can help to identify the presence of a drug-resistant or unusual pathogen and should be obtained from all critically ill patients who are intubated.¹ UAT for pneumococcus or *Legionella* has some potential value for providing a rapid diagnosis. *Legionella* urinary

TABLE 74-5 Diagnostic Testing for Community-Acquired Pneumonia

| TEST | SENSITIVITY | SPECIFICITY | COMMENT |
|---|--------------------------------|------------------------------|---|
| Chest radiograph | 65%-85% | 85%-95% | Computed tomography is more sensitive to infiltrates. Recommended for all patients. |
| Computed tomography | Gold standard | Not infection specific | Should not be performed routinely but helpful to identify cavitation and loculated pleural fluid. Recommended in the evaluation of nonresponding patients. |
| Blood cultures | 10%-20% | High when positive | Usually shows pneumococcus (in 50%-80% of positive samples) and defines antibiotic susceptibility. Recommended in patients with severe CAP, particularly if not on antibiotic therapy at the time of testing. |
| Sputum Gram stain | 40%-100% depending on criteria | 0-100% depending on criteria | Can correlate with sputum culture to define predominant organism and can be used to identify unsuspected pathogens. Recommended if sputum culture is obtained. May not be able to narrow empiric therapy choices. |
| Sputum culture | | | Use if suspect drug-resistant or unusual pathogen, but a positive result cannot differentiate colonization from infection. Obtain via tracheal aspirate in all intubated patients. |
| Oximetry or arterial blood gas | | | Define both severity of infection and need for oxygen; if hypercarbia is suspected, a blood gas sample is needed. Recommended in severe community-acquired pneumonia. |
| Serologic testing for <i>Legionella</i> , <i>Chlamydia pneumoniae</i> , <i>Mycobacterium pneumoniae</i> , viruses | | | Accurate, but usually requires acute and convalescent titers collected 4 to 6 weeks apart. Not routinely recommended. |
| <i>Legionella</i> urinary antigen | 50%-80% | | Specific to serogroup 1, but the best acute diagnostic test for <i>Legionella</i> . |
| Pneumococcal urinary antigen | 70%-100% | 80% | False positives if recent pneumococcal infection. Can increase sensitivity with concentrated urine. |
| Serum procalcitonin | | | Not a routine test, but if performed, should be measured with the highly sensitive Kryptor assay. May help guide duration of therapy and need for ICU admission. |

antigen is specific to serogroup 1 infection and is positive in a little more than half of all infected patients; however, it is the test that is most likely to be positive in the setting of acute illness.¹³⁹ UAT is also available for detecting the capsular polysaccharide of *S. pneumoniae* and has 77% to 88% sensitivity in patients with bacteremic pneumococcal pneumonia but only 64% sensitivity in those with nonbacteremic pneumonia.^{88,140} The sensitivity of pneumococcal UAT increases if concentrated urine is examined, and it can be positive even in the presence of antibiotic therapy; however, false-positive tests can occur in patients who have had recent pneumococcal infection.¹⁴¹ The role of Gram's stain of sputum to guide initial antibiotic therapy is controversial, but this test has its greatest value in guiding the interpretation of sputum culture and can be used to define the predominant organism present in the sample. Gram's stain can be used to broaden initial empiric therapy by enhancing the suspicion for organisms that are not covered in routine empiric therapy (such as *S. aureus* being suggested by the presence of clusters of gram-positive cocci, especially during a time of epidemic influenza).¹

Routine serologic testing is not recommended.¹ Nucleic acid amplification tests and PCR assays provide rapid test results in CAP for atypical agents such as viruses, *Mycoplasma*, *Chlamydia*, and *Legionella*. The usefulness of PCR assays in managing CAP has not been proven, and the concern with this method is that it is so sensitive that, if a respiratory sample is positive, it cannot distinguish colonization from infection. However, the test may be valuable if negative, because the absence of a suspected pathogen by PCR may permit a more focused antibiotic therapy approach. Biomarkers, as mentioned earlier, are helpful in antibiotic stewardship, and a low serum PCT concentration (<0.1 µg/L) may be helpful to support a decision to withhold or discontinue antibiotics.⁷⁶

Bronchoscopy is not indicated as a routine diagnostic test and should be restricted to immunocompromised patients and selected individuals with SCAP. Several studies^{142,143} have not shown any improvement in outcome when a specific etiologic diagnosis is made for patients with SCAP. Rather, the outcome is improved if the initial empiric therapy is accurate and the patient has prompt clinical improvement.¹⁴³ However, patients who have rapidly progressive lung infection despite therapy may benefit from invasive diagnostic testing, but again, a favorable impact of this testing on patient outcome has not been demonstrated. One population that should be considered for invasive testing is corticosteroid-treated COPD patients who have slowly responding or nonresponding pneumonia, because these individuals are at risk for infection with *Aspergillus* and this organism can be recovered from bronchoscopic samples. In addition, bronchoscopy may have value for the nonresponding patient or other immunosuppressed individuals.¹⁴⁴

In patients with SCAP, diagnostic testing may be valuable for guiding modifications of antibiotic therapy, rather than affecting the choice of initial therapy.¹⁴⁵ In one study, nearly 40% of patients had no pathogens identified, and pathogen-directed therapy had no overall impact on mortality or LOS, but led to fewer adverse events than empiric therapy and was also accompanied by a lower mortality for patients admitted to the ICU.¹⁴⁶ In addition, studies have emphasized the mortality benefit of prompt administration of effective antibiotic therapy.¹⁴⁷ Thus, therapy should never be delayed for the purpose of diagnostic testing, and the diagnostic workup should be streamlined, with all patients receiving empiric therapy based on algorithms as soon as possible.

TREATMENT

Initial antibiotic therapy for SCAP is necessarily empiric, with the goal of targeting the likely etiologic pathogens, based on the considerations in Tables 74-3 and 74-4, which categorize patients on the basis of the severity of illness and risk factors for specific pathogens. The likelihood of infection by organisms such as DRSP, enteric gram-negative organisms, and *P. aeruginosa* is determined by the presence of

TABLE 74-6

Empiric Therapy Regimens for Severe Community-Acquired Pneumonia

NO PSEUDOMONAL RISK FACTORS

Selected beta-lactam (cefotaxime, ceftriaxone)

plus

Intravenously administered macrolide or quinolone (moxifloxacin or levofloxacin*)

PSEUDOMONAL RISK FACTORS PRESENT

Selected antipseudomonal beta-lactam (cefepime, piperacillin/tazobactam, imipenem, meropenem)

plus

Ciprofloxacin

or

Selected antipseudomonal beta-lactam

plus

Aminoglycoside

plus

Intravenously administered macrolide or antipseudomonal quinolone (moxifloxacin or levofloxacin*)

NOTE: Although routine methicillin-resistant *Staphylococcus aureus* (MRSA) coverage is NOT recommended for all severe community-acquired pneumonia, consider community-acquired MRSA, especially after influenza and with bilateral necrotizing pneumonia, and if suspected, treat by adding either linezolid or the combination of vancomycin and clindamycin.

*For patients with normal renal function, the recommended dose of levofloxacin is 750 mg daily.

cardiopulmonary disease or “modifying factors.”¹ Although a set of likely pathogens can be predicted for each patient (Table 74-3), and this information can be used to guide initial empiric therapy, if diagnostic testing shows the presence of a specific pathogen, then therapy can be focused.

In choosing empiric therapy of CAP, certain principles and therapeutic approaches should be followed (Table 74-6).^{1,148} All individuals should be treated for DRSP and atypical pathogens, but only those with appropriate risk factors (see earlier) should have coverage for *P. aeruginosa*, and patients with bilateral necrotizing pneumonia after influenza need coverage for CA-MRSA.¹ All patients admitted to the ICU require combination therapy using a beta-lactam with either a macrolide or quinolone, plus the addition of other agents, depending on the clinical setting.^{1,149} The recommendation to avoid monotherapy is based on the fact that the efficacy (especially for meningitis complicating pneumonia), effective dosing, and safety of any single agent, including quinolone monotherapy, has not been established for ICU-admitted CAP patients. From the available data, it appears that adding either a macrolide or quinolone leads to similar results, although some data in patients with bacteremic CAP, especially with pneumococcus, suggest that a macrolide may have particular advantages, possibly because of its antiinflammatory effects.^{101,102,150,151}

In one study of 529 patients with ICU-admitted CAP, combination therapy with a beta-lactam plus either a macrolide or quinolone led to improved survival for the population with shock needing pressors (279 patients), compared with the use of monotherapy.¹⁵² Another study in SCAP patients (not all pneumococcal) also confirmed the benefit of adding a macrolide as part of the initial empiric therapy, but not a quinolone, for reducing mortality.¹⁵³ In a recent study comparing the impact of dual (β-lactam plus macrolide or fluoroquinolone [n = 394]) versus monotherapy (β-lactam alone [n = 471]) in immunocompetent SCAP, there was no difference in the 60-day mortality between the two groups.¹⁵⁴ However, there was a survival advantage for patients who had initial adequate antibiotic therapy, and those who received dual therapy had a higher frequency of initial adequate antibiotics. In one study comparing high-dose levofloxacin to a beta-lactam/quinolone combination, the single-agent regimen was effective overall. However, patients in septic shock were excluded, and there was a trend to a worse outcome with monotherapy for individuals receiving MV.¹⁴⁹ In a meta-analysis of SCAP, the addition of a macrolide to a beta-lactam was associated with

reduced mortality compared with other regimens.¹⁵⁵ If *Legionella* is suspected, then the use of a quinolone may be preferable, since these agents have been highly successful in treating pneumonia caused by this organism and may possibly be more effective than macrolides.¹⁵⁶

For patients with pseudomonal risk factors, therapy can be with a two-drug regimen, using an antipseudomonal beta-lactam (cefepime, imipenem, meropenem, piperacillin/tazobactam) plus ciprofloxacin (the most active antipseudomonal quinolone) or levofloxacin. Alternatively, a three-drug regimen can be used, combining an antipseudomonal beta-lactam plus an aminoglycoside plus either an intravenous antipneumococcal quinolone (moxifloxacin or levofloxacin) or a macrolide.¹ If CA-MRSA is suspected, therapy can be with either vancomycin or linezolid, although other agents might be effective, since this pathogen is not as antibiotic resistant as nosocomial MRSA. However, since CA-MRSA is in part a toxin-mediated illness, the use of an agent that inhibits toxin production, along with an antibacterial effect, is recommended by some.¹⁰⁴ To do this, linezolid can be used alone (since it acts to inhibit protein synthesis), or clindamycin can be added to vancomycin.

HCAP patients can be treated in the same manner as other SCAP patients, but some will need coverage for nosocomial pneumonia pathogens, including MDR gram-negatives and nosocomial MRSA.¹⁰⁵ The benefit of a macrolide in reducing mortality may not be as dramatic in HCAP patients as in CAP patients.¹⁵⁷ Those who need coverage for MDR organisms are individuals with severe HCAP who have an additional risk factor (besides just residence in a nursing home), while those without such risk factors can receive the SCAP regimens. The risk factors for MDR pathogen infection include poor functional status, immune suppression, recent antibiotic therapy, or recent hospitalization.¹⁰⁵ Those at risk for MDR pathogens should receive dual antipseudomonal therapy (beta-lactam plus an aminoglycoside) plus MRSA coverage (linezolid or vancomycin). Maruyama and colleagues prospectively applied an algorithm based on the presence of MDR risk factors (immunosuppression, hospitalization within the past 90 days, poor functional status: Barthel Index score < 50, and antibiotic therapy within the past 6 months) and severity of illness (requiring ICU admission or MV) to determine outcomes on CAP and HCAP patients.¹⁵⁸ Using the algorithm, the investigators used CAP therapy for HCAP patients with 0-1 risk factors and the hospital acquired pneumonia (HAP) regimen for more than two risk factors, but the majority (92.9%) received appropriate therapy for the identified pathogens, and thus, broader spectrum antibiotics can be potentially limited even in patients with HCAP.

Although they should not be used as monotherapy for ICU-admitted CAP patients, antipneumococcal quinolones have assumed great importance because they can cover pneumococcus (including DRSP), nonpseudomonal gram-negative organisms, and atypical pathogens.¹ Quinolones penetrate well into respiratory secretions and are highly bioavailable, achieving the same serum levels with oral or intravenous therapy, and thereby allowing a rapid switch to oral therapy in responding patients. The available intravenous agents that are active against pneumococcus are moxifloxacin and levofloxacin.¹⁵⁹ Based on *in vitro* activity, the recommended doses for moxifloxacin and levofloxacin are 400 mg daily and 750 mg daily, respectively, with the need to adjust dosing of levofloxacin (but not moxifloxacin) in patients with renal insufficiency.

Timeliness of Initial Therapy

For inpatients with CAP, timely and accurate therapy is essential to reduce mortality. In patients with SCAP, improved survival has been shown to occur if initial empiric therapy is accurate and if it leads to a rapid clinical response.^{99,143,147} In one study, if initial therapy led to a clinical response within 72 hours, mortality of SCAP was approximately 10%, compared with a mortality rate of 60% in patients who had initially ineffective therapy.¹⁴³ For CAP in general, early therapy is associated with reduced mortality compared with therapy given later; if the patient has pneumonia with sepsis and hypotension, mortality rises by nearly 8% for every hour of delay in starting therapy.¹⁶⁰

Duration of Therapy

There is little information on the proper duration of therapy in patients with CAP, especially those with severe illness. Even in the presence of pneumococcal bacteremia, short durations of therapy may be possible, with a rapid switch from intravenous to oral therapy in responding patients.¹⁶¹ Generally, *S. pneumoniae* can be treated for 5 to 7 days if the patient is responding rapidly and has received the correct dose of an accurate therapy. The presence of extrapulmonary infection (e.g., meningitis) and the identification of certain pathogens (such as bacteremic *S. aureus* and *P. aeruginosa*) may require a longer duration of therapy. Identification of *L. pneumophila* pneumonia may require at least 14 days of therapy, depending on the severity of illness and host defense impairments, but shorter durations with quinolone therapy have been shown to be effective. Most therapy in the ICU will be given intravenously; however, recent studies, using a variety of antibiotics, have suggested that oral therapy may be instituted after as early as 2 to 3 days of parenteral therapy, assuming that the patient's condition has stabilized and the patient is afebrile.¹ The switch to oral therapy, even in severely ill patients, may be facilitated by the use of quinolones that are highly bioavailable and achieve the same serum levels with oral therapy as with intravenous therapy.

The initial PCT level may accurately predict a positive blood culture in pneumonia patients, and serial measurements help with antibiotic de-escalation and withdrawal in CAP patients.^{162,163} In a randomized trial of antibiotic therapy in the ICU, PCT guidance led to a reduction in the duration of therapy compared with standard care in all patients, including those with SCAP.¹⁶⁴ A recent meta-analysis of 14 randomized trials favored a PCT-based treatment algorithm for antibiotic de-escalation without an increase in either mortality or treatment failure.¹⁶⁵

Adjunctive Therapy Measures

In addition to antibiotic therapy, patients with SCAP may require chest physiotherapy, especially if they have either an excessive volume of purulent sputum (>30 mL/day) or severe respiratory muscle weakness resulting in ineffective cough.¹⁶⁶ Aerosolized humidification has been used to reduce sputum viscosity, thereby enhancing clearance in patients who have generally ineffective cough. However, it is likely that much of the generated water vapor is deposited in the upper airway, where it is likely to stimulate cough but unlikely to influence the rheologic properties of the sputum. Bronchodilator therapy, which also enhances mucociliary clearance and ciliary beat frequency, is most likely to be of benefit in patients with pneumonia complicating COPD. A recent Cochrane review did not find convincing evidence supporting the role of chest physiotherapy in pneumonia patients.¹⁶⁷

Previous studies looking into the use of adjunctive corticosteroids in patients with SCAP have shown mixed results.^{168,169} Although the role of corticosteroids in the routine therapy of CAP is not established, steroids may be beneficial in patients with sepsis and relative adrenal insufficiency, which occurs in a high proportion of patients with SCAP.¹⁷⁰ A recent meta-analysis of nine trials involving 1001 patients did not support the routine use of corticosteroids in CAP patients, but showed that it may improve mortality in a subset with SCAP.¹⁷¹ Another setting in which corticosteroids may have benefit is in pneumococcal pneumonia that is complicated by meningitis, where pretreatment with corticosteroids prior to antibiotic therapy may lead to more favorable neurologic outcomes.¹⁷² Recently, Torres and associates, in a randomized, prospective study, found that in patients with SCAP and elevated C-reactive protein > 150 mg/L at admission, administration of intravenous methylprednisolone (bolus of 0.5 mg/kg per 12 hours) led to less treatment failure compared with placebo.¹⁷³ In that study, there was no significant difference in hospital mortality between the two groups. Adjunctive immune therapy with granulocyte colony-stimulating factor has also been used in SCAP, with no benefit in mortality or in the course of illness resolution.¹⁷⁴

Evaluation of Response to Therapy

The majority of patients will respond rapidly to accurate empiric therapy within 24 to 72 hours. Clinical response is defined as improvement in the symptoms of cough, sputum production, and dyspnea, along with the ability to take medications orally, declining white blood cell count, and an afebrile status on at least two occasions 8 hours apart.¹ In the critically ill patient, improvement in oxygenation may be one of the earliest signs of response to therapy, although few studies have examined MV patients.¹ Radiographic improvement lags behind clinical improvement and, in general, 50% of patients with pneumococcal pneumonia have radiographic clearing at 5 weeks, whereas the majority clears in 2 to 3 months. With bacteremic disease, 50% of patients have a clear chest radiograph at 9 weeks, and most are clear by 18 weeks.¹⁷⁵ Radiographic resolution is most influenced by the number of lobes involved and the age of the patient. Radiographic clearance of CAP decreases by 20% per decade after the age of 20 years, and patients with multilobar infiltrates take longer to clear than those with unilobar disease.¹⁷⁵

If the patient fails to respond to appropriate therapy during the expected time interval, then it is necessary to consider infection with a drug-resistant or unusual pathogen (tuberculosis, *C. burnetii*, *Burkholderia pseudomallei*, *C. psittaci*, endemic fungi, or hantavirus), a pneumonic complication (lung abscess, endocarditis, empyema), or a noninfectious process that mimics pneumonia (bronchiolitis obliterans with organizing pneumonia, hypersensitivity pneumonitis, pulmonary vasculitis, bronchoalveolar cell carcinoma, lymphoma, pulmonary embolus).¹ The evaluation of the nonresponding patient should be individualized but may include CT of the chest, pulmonary angiography, bronchoscopy, and, occasionally, open lung biopsy.

PREVENTION

Prevention of CAP is important for all population groups but especially the elderly patient, who is at risk for both a higher frequency of infection and a more severe course of illness. Appropriate patients should be vaccinated with both pneumococcal and influenza vaccines, and cigarette smoking should be stopped in all at-risk patients. Even for the patient who is recovering from CAP, immunization while in the hospital is appropriate to prevent future episodes of infection, and the evaluation of all patients for vaccination need and the provision of information about smoking cessation have been performance standards used to evaluate the hospital care of CAP patients.¹

Pneumococcal Vaccine

Pneumococcal capsular polysaccharide vaccine can prevent pneumonia in otherwise healthy populations, as was initially demonstrated in South African gold miners and American military recruits.^{1,176} The benefits in individuals of advanced age or with underlying conditions in nonepidemic environments are less clearly defined. The polysaccharide vaccine efficacy has ranged from 65% to 84% in patients with diabetes mellitus, coronary artery disease, congestive heart failure, chronic pulmonary disease, and anatomic asplenia.¹⁷⁶ In immunocompetent patients over the age of 65 years, effectiveness has been documented to be 75%. In the immunocompromised patient, effectiveness has not been proven, and this includes patients with sickle cell disease, chronic renal failure, immunoglobulin deficiency, Hodgkin's disease, lymphoma, leukemia, and multiple myeloma. A single revaccination is indicated in a person who is older than 65 years of age who initially received the vaccine more than 5 years earlier and was younger than 65 years of age at the first vaccination.^{1,90} If the initial vaccination was given at the age of 65 years or older, a repeat vaccination is not indicated unless the patient has anatomic or functional asplenia or has one of the immunocompromising conditions listed earlier. In these patients, revaccination is indicated, and the second dose is given at least 5 years after the original dose.

The available polysaccharide pneumococcal vaccine is widely underutilized, especially as the 23-valent pneumococcal vaccine contains 23 pneumococcal serotypes that cause 85% of all infections due to pneumococcus. Two protein-conjugated pneumococcal vaccines have been licensed, and are more immunogenic than the older vaccine, but contain only 7 and 13 serotypes.¹ However, the conjugate vaccine has had benefit for adults, even when given to only children, demonstrating a "herd immunity" effect.¹⁷⁷ The 13-valent pneumococcal conjugate vaccine (PCV13) was approved by the Food and Drug Administration in late 2011 for use among adults aged ≥ 50 years.¹⁷⁸ Based on the recent report from the randomized, placebo-controlled trial evaluating the efficacy of PCV13 for preventing CAP among adults aged ≥ 65 years (CAPITA: Community-Acquired Pneumonia Immunization Trial in Adults), the Advisory Committee on Immunization Practices recommended routine use of PCV13 among adults aged ≥ 65 years from August 2014.¹⁷⁸ PCV13 should be administered in series with the 23-valent pneumococcal polysaccharide vaccine, giving PCV13 first, if possible. PCV13 and 23-valent pneumococcal polysaccharide vaccine vaccination are also recommended in patients with chronic pulmonary diseases on steroids or receiving immunomodulating therapy or who have concurrent sickle cell disease or other hemoglobinopathies, primary immunodeficiency disorders, HIV infection/AIDS, nephrotic syndrome, and hematologic or solid malignancies.¹⁷⁹

Hospital-based immunization could be highly effective, because over 60% of all patients with CAP have been admitted to the hospital, for some indication, in the preceding 4 years, and hospitalization could be defined as an appropriate time for vaccination. Pneumococcal vaccine can be given simultaneously with other vaccines, such as influenza vaccine, but each should be given at a separate site, and the vaccine can, and often should, be given before discharge in the patient admitted for CAP.

Influenza Vaccination

Influenza epidemics contribute to both morbidity and mortality by causing direct infection and by leading to postinfluenza complications. The influenza vaccine preparations are revised annually to account for changes in the antigenic nature of the virus (antigenic drift) that occurs each season. Three strains are represented in each vaccine preparation: two influenza A strains (H3N2 and H1N1) and one influenza B strain. Vaccination should be given to all patients older than the age of 65 years and to those with chronic medical illness (including nursing home residents) and to those who provide health care to patients at risk for complicated influenza.¹ It is given yearly, usually between September and mid-November. While the traditional influenza vaccine contains an inactivated virus, there is now an intranasal vaccine containing a live attenuated influenza virus. It is currently approved for individuals aged 5 to 49 years who are not immune suppressed or chronically ill and who do not have asthma. When the vaccine matches the circulating strain, it can prevent illness in 70% to 90% of healthy persons younger than the age of 65 years.^{1,180} For older persons with chronic illness, the efficacy is lower, but the vaccine can still attenuate the influenza infection, lead to fewer lower respiratory tract infections, and reduce the associated morbidity and mortality that follow influenza. In many studies, the vaccine has been shown to be cost-effective and able to prevent severe illness and death and to reduce the occurrence of secondary pneumonia and hospitalization.¹⁸⁰ For those above 65 years of age, a higher dose influenza vaccine (60 μ g of hemagglutinin per strain) has been shown to provide better protection.^{181,182} In a randomized study including 31,989 participants, the high-dose vaccine induced significantly higher antibody responses and provided better protection against laboratory-confirmed influenza illness than the standard vaccine.¹⁸¹ In another study, Izurieta and colleagues, from a large Medicare database of participants aged ≥ 65 years, found that those who had received high-dose inactivated influenza vaccine during the 2012-2013 influenza seasons were less likely to have influenza-related medical encounters and hospitalization than those who had received the standard-dose vaccine.¹⁸³

KEY POINTS

1. Community-acquired pneumonia (CAP) is a common illness, but only about 20% of all affected patients are admitted to the hospital, and only 10% to 20% of admitted patients require ICU care.
2. Risk factors for severe CAP include smoking, alcohol abuse, serious comorbid medical illnesses, and advanced age.
3. Risk factors for CAP mortality include severe physiologic abnormalities, delays in the initiation of appropriate antibiotic therapy, advanced age, genetic abnormalities in the immune response, rapid radiographic progression, the development of respiratory failure, and the presence of certain high-risk pathogens.
4. Prognostic scoring systems are useful for predicting CAP mortality but are less accurate for identifying patients who require ICU care. ICU care is needed for patients with respiratory failure, multilobar infiltrates, severe hypoxemia ($\text{PaO}_2/\text{FiO}_2$ ratio < 250), and systolic blood pressure lower than 90 mm Hg. Early recognition of severe CAP may allow the ICU to be used in a fashion that can reduce the mortality of this illness.
5. The failure to localize infection to a single site in the lung, with excessive systemic and pulmonary inflammation, is a common feature in patients with severe forms of CAP.
6. The clinical features of pneumonia cannot help to predict the microbial etiology, especially in older patients with impaired immune response who commonly have less dramatic clinical findings than younger patients with a similar severity of illness.
7. The most common pathogens causing severe CAP include pneumococcus, atypical pathogens (*Legionella* spp., *Mycoplasma pneumoniae*, and *Chlamydia pneumoniae*), enteric gram-negatives (including *Pseudomonas aeruginosa*), *Staphylococcus aureus* (including community-acquired methicillin-resistant strains), and *Haemophilus influenzae*, but infection can also be the result of viral illness (influenza, severe acute respiratory syndrome), bioterrorism (anthrax), and other miscellaneous organisms.
8. Antibiotic-resistant pneumococci are increasingly common and must be considered in the choice of initial antibiotic therapy for severe CAP, but the impact of resistance on the outcomes of patients is uncertain.
9. It may be difficult to establish an exact etiologic diagnosis in patients with severe CAP, but diagnostic testing should always include a chest radiograph, oxygenation assessment, blood cultures, and, in selected patients, sputum Gram's stain and culture, bronchoscopic culture, and urinary antigen testing for *Legionella* and pneumococcus.
10. Therapy for severe CAP must be administered promptly and empirically, using multiple antibiotics directed against pneumococcus, atypical pathogens, enteric gram-negative organisms, and, in some patients, *P. aeruginosa* and community-acquired methicillin-resistant *S. aureus*. This usually requires the combination of a specific beta-lactam with either a macrolide or a quinolone and sometimes the addition of other agents. Quinolone monotherapy is not recommended for the empiric management of severe CAP. In patients with severe CAP after influenza, community-acquired methicillin-resistant *S. aureus* should be considered.
11. Biomarkers such as procalcitonin may help identify bacterial infection, and serial measurements will help with antibiotic stewardship.
12. Nonresponse in severe CAP can be recognized as early on as 24 to 48 hours and requires consideration of unusual or drug-resistant pathogens, noninfectious diseases that mimic pneumonia, and pneumonia complications.
13. Prevention of pneumonia can be accomplished by focusing on smoking cessation and immunization for pneumococcus and influenza, with consideration of a hospital-based immunization program. The 13-valent pneumococcal conjugate vaccine (PCV13) was approved by the Food and Drug Administration in late 2011 for use among adults aged ≥ 50 years, and recent evidence suggests using PCV13 in series with the 23-valent pneumococcal polysaccharide vaccine among patients ≥ 65 years of age.

DEFINITIONS

Nosocomial pneumonia is an infection of the pulmonary parenchyma caused by pathogens present in hospital settings.¹ Nosocomial pneumonia develops in patients admitted to the hospital for more than 48 hours, and the incubation period is usually no longer than 2 days. Among nosocomial pneumonias, ventilator-associated pneumonia (VAP), which will be the main focus of this chapter, develops in intensive care unit (ICU) patients who have been mechanically ventilated for at least 48 hours. In contrast, ventilator-associated tracheobronchitis (VAT) is characterized by signs of respiratory infection, without new radiologic infiltrates.² Healthcare-associated pneumonia (HCAP) develops in patients who are not hospitalized,¹ but have risks for being colonized by nosocomial multidrug-resistant (MDR) pathogens. Risk factors for developing HCAP are hospitalization for 2 days or more within the preceding 90 days, residence in a nursing home or extended care facility, home infusion therapy, chronic dialysis, home wound care, and contact with subjects colonized by MDR pathogens. Several North American studies³ have reported that MDR microorganisms primarily cause HCAP; conversely, European data⁴ show greater similarity in microbiology with community-acquired pneumonia.

Nosocomial pneumonia is classified based on the presence of microorganisms isolated from respiratory surveillance cultures and includes the following categories⁵:

1. Primary endogenous pneumonia: causative microorganisms are isolated in surveillance cultures on admission.
2. Secondary endogenous pneumonia: causative microorganisms are nosocomial pathogens not present on admission but have colonized the patient during a hospital stay.
3. Exogenous pneumonia: caused by microorganisms not originally isolated from surveillance cultures; hence the patient is not a previous carrier.

The time of onset for nosocomial pneumonia reflects possible etiologies, empirical antimicrobial treatment, and outcomes. Previously, VAP has been categorized as either early or late onset.⁶ In an interesting trial by Trouillet et al.,⁷ three variables were significant for predicting infection with MDR: duration of mechanical ventilation (MV) ≥ 7 days (odds ratio [OR] = 6.0), prior antibiotic use (OR = 13.5), and prior use of broad-spectrum antimicrobial agents (OR = 4.1). More recent reports⁸⁻¹¹ challenge this classification. Indeed, investigators recently have found comparable microbial etiologies between patients with early or late-onset VAP. This may be related to the worldwide rise in MDR and emphasizes that the local ICU ecology is the most important risk factor for acquiring MDR pathogens, irrespective of the length of intubation.

EPIDEMIOLOGY

Incidence and Associated Burden

Nosocomial pneumonia is the second most common nosocomial infection and the leading cause of death from nosocomial infections among critically ill patients. Incidence ranges from 5 to more than 20 cases per 1000 hospital admissions,¹ with the highest rates in immunocompromised, surgical, and elderly patients. Approximately

one-third of nosocomial pneumonias are acquired in the ICU, with VAP being the majority of these ICU-acquired pneumonias. Epidemiology studies from United States report a VAP incidence density between 2 and 16 episodes per 1000 ventilator-days.¹² In comparison with previous reports, the incidence of VAP is decreasing,¹³ likely due to better implementation of prophylactic strategies. Cook et al.¹⁴ estimated that the risk of VAP is 3% during the first 5 days on MV, 2% from the 5th to the 10th days, and 1% for subsequent days. Nosocomial pneumonia, and particularly VAP, increases the duration of hospitalization and healthcare costs. Worsened clinical outcomes associated with VAP have been consistently reported throughout the years.^{15,16} As a result, mean hospital charges per VAP patient have been estimated to increase by approximately US\$40,000.^{15,16}

Mortality

The crude mortality from nosocomial pneumonia may be as high as 30% to 70%.¹ Several reports have estimated that one-third to one-half of all VAP-related deaths are the direct result of the infection, with a higher mortality rate in cases caused by *Pseudomonas aeruginosa*¹⁷ and *Acinetobacter* spp.¹⁸ Attributable VAP mortality has been defined as the percentage of deaths that would not have occurred in the absence of the infection. Recent studies have reappraised the impact of VAP on mortality.¹⁹⁻²¹ In particular, as mentioned earlier, the risk of VAP is time-dependent, possibly causing a significant time-dependent bias, because mortality and ICU discharge act as competing endpoints. Thus, the most recent studies reported an attributable mortality associated with VAP of 10%,^{21,22} with surgical patients and patients with mid-range severity of illness at the highest associated risk.

PATHOGENESIS

Extensive laboratory and clinical work have determined the key pathogenic mechanisms of VAP. Pathogens must first gain access to the airways to cause pneumonia, and intubated patients are at high risk for aspiration of colonized oropharyngeal secretions. In healthy, nonintubated patients, when bacteria gain access to the respiratory tract, colonization is prevented through defense mechanisms, such as a cough, mucus clearance, and cellular and humoral immune responses. Critically ill and intubated patients are already at a high risk for infection because of underlying illness, comorbidities, malnutrition, and invasive devices or procedures. However, tracheal intubation is the *conditio sine qua non* for the development of VAP, because it facilitates aspiration of pathogens and hinders intrinsic respiratory defenses.

Role of the Endotracheal Tube in the Pathogenesis of VAP

Pulmonary aspiration of the colonized oropharyngeal secretions across the endotracheal tube (ETT) cuff is the main pathogenic mechanism for the development of VAP. The most commonly used ETT for long-term mechanically ventilated patients comprises a high-volume, low-pressure (HVLP) cuff. HVLP cuffs were originally designed to prevent tracheal injury.²³ However, the diameter of the HVLP cuff is two to three times larger than the tracheal diameter, so when the ETT cuff is

FIGURE 75-1 ■ Laboratory studies to assess biofilm formation on the internal surface of the tracheal tube, following oropharyngeal challenge in pigs of *Pseudomonas aeruginosa* (strain PAO1) and 72 hours of mechanical ventilation. **A**, Internal surface of the tracheal tube at extubation, largely covered by respiratory secretions. **B**, Cross-section of tracheal tube stained with LIVE/DEAD BacLight bacterial viability kit and imaged with confocal scanning laser microscopy. Bacterial biofilm adheres to internal ETT surface. White arrows indicate bacteria embedded into biofilm matrix. **C**, Scanning electron microscopy of tracheal tube lumen. Note the presence of amorphous deposits on most of the surface. **D**, Higher magnification of tracheal tube lumen through scanning electron microscopy. *P. aeruginosa* sessile cells are clearly visible within biofilm extracellular polymeric substance. ETT, endotracheal tube.

inflated within the trachea, folds invariably form along the cuff surface, causing consistent aspiration of oropharyngeal secretions.²⁴

Pathogens may also grow on the internal surface of the ETT and ultimately translocate into the lungs. Bacteria easily adhere to the ETT internal surface to form a structure called a *biofilm*²⁵ (Fig. 75-1). Biofilm is composed of sessile bacteria embedded within a self-produced exopolysaccharide matrix.²⁶ Biofilm on the internal surface of an ETT can be identified early following tracheal intubation.²⁷⁻²⁹ Sessile bacteria undergo phenotypic differentiation from their planktonic counterparts to improve survival. Indeed, sessile bacteria are difficult to eradicate by the host's immune response or antibiotics.³⁰ During MV, biofilm particles may dislodge into the airways as a result of the inspiratory airflow²⁵ and invasive medical interventions, such as tracheal aspiration.³¹ Several studies^{27-29,32} have confirmed that the ETT biofilm constitutes a persistent source of colonization.

Sources of Colonization

Patients are colonized exogenously by contaminated respiratory equipment, the ICU environment, and the hands of the ICU staff. Several reports have described ICU outbreaks due to colonized bronchoscopes,^{33,34} water supply,³⁵ respiratory equipment,³⁶ humidifiers,³⁷ ventilator temperature sensors,³⁸ respiratory nebulizers,³⁹ and the contaminated ICU environment.⁴⁰

Endogenous colonization is the primary pathogenic mechanism for VAP development. In the critically ill patient, the oral flora shifts early to a predominance of aerobic gram-negative pathogens,⁴¹ *P. aeruginosa*, and methicillin-resistant *Staphylococcus aureus* (MRSA). Pulmonary aspiration of oropharyngeal contents increases the risk for airway colonization and infection. Following aspiration and colonization of the airways, the occurrence of VAP primarily depends on the size of the inoculum, functional status of the patient, and the competency of host defenses. There remains controversy regarding the exact

sequence of colonization and source of infection in the pathogenesis of VAP. Early studies by Feldman et al.⁴² found that in patients undergoing MV; the oropharynx is the first site to be colonized by pathogens (36 hours), followed by the stomach (36-60 hours), the lower respiratory tract (60-84 hours), and the ETT thereafter (60-96 hours).

Oropharyngeal Colonization

In ICU patients, several oropharyngeal defense mechanisms are dramatically altered. First, comorbidities and inherent patient characteristics, such as alcohol abuse,⁴³⁻⁴⁵ diabetes,^{46,47} and chronic obstructive pulmonary disease (COPD),⁴⁸ are well-known risk factors for Gram-negative oropharyngeal colonization. Elderly patients,⁴⁹⁻⁵² patients with disabilities,⁵³ and patients tracheally intubated for extended periods are at increased risk for overgrowth of oropharyngeal pathogens, because of their inability to carry out effective oral care. Additionally, the extensive use of antibiotics in critical care settings promotes overgrowth of oropharyngeal pathogens.^{54,55} Second, during critical illness, the antimicrobial effectiveness of saliva is highly impaired due to a dramatic reduction in the salivary flow,⁵⁶ decreased pH,⁵⁷ and increased amount of proteases released by host immune cells and periodontal bacteria.⁵⁸⁻⁶⁰ Bacteria that colonize the oropharynx also produce a large variety of hydrolases that lead to increased expression of key receptors for bacterial adhesion.⁶¹⁻⁶³

Fourrier and collaborators⁶⁴ found that prolonged ICU stay increased the risk for oropharyngeal colonization, which ultimately led to nosocomial pulmonary infection. Azarpazhooh et al.⁶⁵ found evidence of an association of pneumonia with oral health (OR = 1.2 to 9.6, depending on oral health indicators); improved oral hygiene reduced the occurrence of respiratory infection among high-risk elderly adults. Interestingly, in a study by Heo,⁶⁶ oral respiratory pathogens were often genetically identical to pathogens recovered from the lower airways, and rapid changes of bacterial species in both oral and pulmonary sites occurred.

Sinuses

The association between sinusitis and VAP has long been debated.⁶⁷ Several studies have confirmed that orotracheal as compared to nasotracheal intubation is associated with a decreased incidence of sinusitis⁶⁸⁻⁷⁰ and that the incidence of VAP is lower in patients who do not develop sinusitis.⁷¹ A study by Holzapfel et al.⁷² evaluated the incidence of nosocomial maxillary sinusitis and pneumonia in patients who underwent either nasotracheal or orotracheal intubation. The authors found that sinusitis increased the risk of nosocomial pneumonia by a factor of 3.8.

Stomach

According to the gastropulmonary hypothesis of colonization, the stomach of ICU patients is colonized by pathogens due to gastric alkalization associated with enteral nutrition and drugs for prevention of gastrointestinal bleeding.⁷³ Continuous gastroesophageal reflux facilitates translocation of microbes into the oropharynx, which is then aspirated across the ETT cuff. Early studies have shown that in tracheally intubated patients, gastric pH higher than 4 was consistently associated with gastric colonization.^{74,75} However, the association between gastric colonization and VAP found in early studies⁷⁶⁻⁷⁸ has been challenged.^{79,80} Overall, this area remains highly controversial, and several studies^{42,79,81-84} have not found a relationship with bacteria causing VAP as first originating in the stomach.

Impairment of Respiratory Defense During Critical Illness and Tracheal Intubation

In healthy subjects, the anatomic laryngeal barrier prevents aspiration of pathogen-laden oropharyngeal contents. Following intubation, the ETT completely bypasses these anatomic barriers. A cough is one of the most efficient mechanisms to prevent further translocation of pathogens that may have gained access to airways. Tracheal intubation prevents the closure of the glottis. Hence, it hinders cough⁸⁵; moreover, intubated patients are often sedated and unable to generate high expiratory flows.

Mucociliary clearance is the primary innate airway defense mechanism to clear pathogens. In young, healthy nonsmokers, the mucociliary velocity ranges between 10 and 20 mm/min. Studies in animals have shown that inflation of the ETT cuff lowers mucociliary velocity by 50% after only 2 hours.⁸⁶ Clinical studies⁸⁷ in critically ill patients have found similar reduced mucociliary velocity (0.8-1.4 mm/min) and higher risks for pulmonary complications.

As previously mentioned, the daily hazard rate for developing VAP is higher during the first days of MV.¹⁴ Investigators have found that a temporary immunoparalysis can be found early in the course of the critical illness and admission to the ICU.⁸⁸ In particular, researchers have assessed human leukocyte antigen-DR (HLA-DR) expression on peripheral monocytes as a marker of immune function.⁸⁹ Low levels of HLA-DR expression have been found in patients who subsequently developed nosocomial pneumonia.⁹⁰

Etiologic Agents for Nosocomial Pneumonia

Nosocomial pneumonia may be caused by a variety of pathogens; also, in many patients, more than one pathogen may be isolated. Microorganisms responsible for nosocomial pneumonia differ according to the ICU population, the duration of hospital and ICU stays, and the specific diagnostic method(s) used. VAP is commonly caused by aerobic pathogens, often MDR, including *P. aeruginosa*, *Acinetobacter* species, carbapenemase-containing *Klebsiella pneumoniae*, and MRSA.¹ Data from 7087 infected patients (63.5% with respiratory tract infection) from the Extended Prevalence of Infection in Intensive Care (EPIC II) study⁹¹ have confirmed that *Pseudomonas* spp. and *S. aureus* are the most common isolated pathogens in ICUs.

Esperatti et al.⁹² prospectively evaluated 315 ICU patients with HAP admitted to an ICU; among those, 52% were invasively ventilated,

whereas 48% were either on spontaneous or noninvasive ventilation (NIV). Interestingly, the proportion of causative pathogens was similar between groups, except for a higher proportion of *Streptococcus pneumoniae* in patients not invasively ventilated. Thus, it seems that in ICU-acquired pneumonia, the overall frequency of MDR pathogens and MRSA is sufficiently high to warrant the use of broad empirical therapy.

The high rate of polymicrobial infection in VAP has been shown repeatedly. Combes and colleagues⁹³ studied 124 ICU patients, of whom 52% had monomicrobial VAP and 48% polymicrobial VAP. In most patients, two different bacterial species were isolated (34%); however, up to four different bacterial species coexisted in 7 patients (6%). Interestingly, no differences were detected in mortality rate at 30 days among patients with polymicrobial or monomicrobial infection. A study by Teixeira et al.⁹⁴ investigated risk factors for inadequate empirical antimicrobial therapy in 151 ICU patients and found that inadequate antimicrobial treatment was associated with polymicrobial VAP (OR = 3.67; 95% confidence interval [CI] = 1.21-11.12; *P* = 0.02), and higher mortality.

Underlying diseases may predispose patients to infection with specific organisms. Patients with COPD are at increased risk for *Haemophilus influenzae*, *Moraxella catarrhalis*, *P. aeruginosa*, or *S. pneumoniae* infections.^{95,96} Patients with acute respiratory distress syndrome (ARDS) are at higher risk for developing VAP caused by *S. aureus*, *P. aeruginosa*, and *Acinetobacter baumannii*, and often in these patients, VAP is caused by multiple pathogens.^{97,98} Finally, trauma and neurologic patients are at increased risk for *S. aureus*, *Haemophilus*, and *S. pneumoniae* infections.⁹⁹⁻¹⁰¹

Causative pathogens of VAP that are potentially multiresistant are *P. aeruginosa*, MRSA, *Acinetobacter* spp., *S. maltophilia*, *Burkholderia cepacia*, and *K. pneumoniae*.⁸ Conversely, *S. pneumoniae*, *H. influenzae*, methicillin-sensitive *S. aureus* (MSSA), and antibiotic-sensitive Enterobacteriaceae are not considered MDR pathogens. In the majority of the cases, resistance to third- and fourth-generation cephalosporins in carbapenem-susceptible strains of *Escherichia coli* and *K. pneumoniae* is caused by the acquisition of plasmidic Ambler class A extended-spectrum β -lactamases or AmpC-like cephalosporinases.¹⁰² Resistance to carbapenems in Enterobacteriaceae is caused by the acquisition of plasmidic carbapenemases, either of Ambler class A (mainly *K. pneumoniae* carbapenemase), B, or D.¹⁰² Importantly, plasmids harboring extended-spectrum β -lactamase (ESBL)-encoding and/or carbapenemase-encoding genes often carry other resistance genes, which ultimately confer pan-drug resistance. Conversely, carbapenem resistance in *P. aeruginosa* and *A. baumannii* may be caused by loss of outer membrane porins, hyperexpression of efflux pump systems, and carbapenemase production. In 2010, linezolid-resistant MRSA was reported,¹⁰³ due to a plasmid harboring the chloramphenicol-florfenicol resistance gene.¹⁰⁴⁻¹⁰⁶

Patients at risk of being colonized by MDR pathogens are extremely heterogeneous, often present several comorbidities, and many receive antibiotics during their hospitalization. The incidence of MDR pathogens is also closely linked to local factors and varies widely from one institution to another.¹⁰⁷ Therefore, clinicians must be aware of their ICU local ecology and antibiotic susceptibility to avoid the administration of inadequate initial antimicrobial therapy.

Legionella pneumophila as the cause of nosocomial pneumonia should be considered, particularly in immunocompromised patients.¹⁰⁸ Often, the source of legionellosis outbreaks within the hospital is a water system that has become colonized by the microorganism.¹⁰⁹

A primary mechanism for VAP development is through aspiration of oropharyngeal contents, and the oropharynx is highly colonized by anaerobes. Robert et al.¹¹⁰ studied 26 mechanically ventilated patients and found that 15 patients became colonized with 28 different anaerobic strains. Similarly, Dore et al.¹¹¹ found anaerobic bacteria in 30 (23%) of 130 patients diagnosed with VAP but always in association with aerobic pathogens. Importantly, empirical antibiotic therapy active against anaerobic bacteria appears to improve short-term outcomes in patients with VAP. Nevertheless, the role of anaerobes in VAP

is still considered to be controversial. In particular, Marik et al.¹¹² studied microbiology of 185 episodes of suspected VAP through blind protected specimen brush (PSB) sampling and mini-BAL and were unable to identify anaerobes as the causative pathogens of VAP.

Rarely, VAP is caused by fungi. *Candida* spp. and *Aspergillus fumigatus*¹¹³ are the most commonly isolated fungi, predominantly in immunocompromised patients. *Candida* promotes the development of pneumonia by creating biofilms that facilitate bacterial colonization.¹¹⁴ Moreover, *Candida* seems to reduce host immune response.¹¹⁵ Thus, clinical studies have shown that *Candida* colonization increases the risk of VAP by *P. aeruginosa*.¹¹⁶ Yet, in a postmortem study of patients with evidence of pneumonia at autopsy and isolation of *Candida* from respiratory samples, no case of *Candida* pneumonia was found.¹¹⁷ Interestingly, colonization by *Candida* has also been associated with longer MV, ICU and hospital stays, and in-hospital mortality.¹¹⁸⁻¹²⁰ Some investigators argue that the presence of *Candida* is merely a marker of severity rather than a true etiologic factor for VAP.¹²¹

Viruses may also cause VAP. Herpes simplex virus type-1 (HSV-1) nosocomial pneumonia is more frequently reported in immunocompromised patients and patients with ARDS,¹²² major surgery,^{123,124} or extensive burns.¹²⁵ Luyt et al. demonstrated in 201 patients with clinical suspicion of VAP that 21% had HSV-1 pneumonia.¹²⁶ Several studies¹²⁷⁻¹³⁰ have reported a high incidence of active CMV infection in mechanically ventilated patients. Chiche et al.¹³⁰ studied 242 immunocompetent ICU patients and found active CMV infection in 39 (16%) individuals. At 28 days, only 15% of the patients with active CMV infection were weaned and alive, in comparison to 52% of patients free of CMV infection ($P < 0.001$).

PREVENTION

Nosocomial pneumonia is associated with high morbidity and mortality and constitutes an important burden for the healthcare system. Therefore, preventive strategies should be implemented to reduce the overall incidence of the disease (Box 75-1). The Institute for Healthcare Improvement recommends that approaches with proven efficacy in infection control should be implemented together as a bundle because combined, they are expected to result in a better outcome than when implemented individually. Designing a preventive bundle is just the first step and must be followed by a continuous assessment of

healthcare personnel compliance and improvements to implement interventions. Several reports¹³¹⁻¹³³ have found consistent reductions in the incidence of VAP following the implementation of VAP preventive bundles.

General Prophylactic Measures

Maintaining high levels of education among ICU personnel relating to VAP pathophysiology and preventive strategies can be effective in reducing its incidence.¹³¹ Needleman et al.¹³⁴ studied administrative data from 799 hospitals in 11 states (covering 5,075,969 discharges of medical patients and 1,104,659 discharges of surgical patients) and found that a higher proportion of hours of care per day provided by registered nurses, compared to licensed practical nurses and nurses' aides, was associated with lower incidence of pneumonia.

Adherence to simple infection-control measures, such as alcohol-based hand disinfection,^{135,136} effectively reduces cross-transmission of pathogens and incidence of VAP. The World Health Organization has endorsed hand hygiene as the single most important element of strategies to prevent healthcare-associated infections.¹³⁷ Overall, most studies conducted in ICUs have shown consistent results and a temporal association between implementation of alcohol-based hand hygiene and reduction of nosocomial infections.^{135,138}

Investigators demonstrated that patient transport outside the ICU was associated with increased risk for VAP.^{139,140} Clinicians and nursing staff should carefully check the internal pressure of the ETT cuff prior to and during patient transport. Also, ventilator circuits should be carefully manipulated to prevent the aspiration of colonized fluids from within the circuit.

Daily interruption or lightening of sedation¹⁴¹⁻¹⁴³ and early mobilization,¹⁴⁴ as well as avoidance of paralytic agents, is highly recommended to avoid impairment of respiratory defenses, prolonged tracheal intubation, and VAP.

There is evidence of shorter length of MV, reduced rate of failed extubation, and decreased incidence of VAP when protocol-driven weaning from the ventilator is implemented.¹⁴⁵⁻¹⁴⁸ Marelich et al.¹⁴⁶ randomized 385 patients to receive either a protocol-driven weaning procedure or standard care and found that duration of MV was decreased from a median of 124 hours for the control group to 68 hours in the protocol-driven weaning group ($P = 0.0001$). Moreover, a trend toward less VAP was found in the treatment group ($P = 0.061$).

NIV

Tracheal intubation and MV account for the main risk for nosocomial pneumonia and should therefore be avoided whenever possible. NIV is an attractive alternative for patients with acute exacerbations of COPD or acute hypoxemic respiratory failure and for some immunocompromised patients with pulmonary infiltrates and respiratory failure.¹⁴⁹⁻¹⁵³ NIV can also be safely used to facilitate early extubation and avoid continued invasive weaning. A meta-analysis¹⁵⁴ confirmed that noninvasive weaning is associated with reduced mortality, VAP, and length of stay in the ICU and hospital. Other reports^{155,156} have emphasized the role of NIV in preventing re-intubation in recently extubated patients at risk for relapse and respiratory failure. Kohlenberg et al.¹⁵⁷ pooled data of 400 ICUs in Germany and found a mean pneumonia incidence of 1.58 and 5.44 cases per 1000 ventilator days for NIV and invasive MV, respectively. Therefore, when indicated, NIV should be attempted to avoid tracheal intubation and reduce the overall duration of tracheal intubation.

Tracheal Tube Cuff

Currently, in critical care settings, patients are intubated with ETT comprising high-volume low-pressure cuffs. Upon inflation, folds form along the cuff surface, and colonized oropharyngeal secretions may leak through these folds. Novel ETT cuffs made of polyurethane,¹⁵⁸ silicone,¹⁵⁹ and latex¹⁶⁰ have been developed and tested in the

BOX 75-1

Preventive Strategies for Nosocomial Pneumonia

- Implementation, as a bundle, of nosocomial pneumonia preventive strategies that have proven efficacy in reducing morbidity and mortality
- Implementation of educational programs for caregivers and frequent performance feedbacks and compliance assessment
- Strict alcohol-based hand hygiene
- Avoidance of tracheal intubation and use of NIV when indicated
- Daily sedation vacation and implementation of weaning protocols
- No ventilatory circuit tube changes unless the circuit is soiled or damaged
- Use of tracheal tube with cuff made of novel materials and shapes
- Use of silver-coated tracheal tube
- Application of low-level PEEP during tracheal intubation
- Aspiration of subglottic secretions
- Internal cuff pressure maintained within the recommended range and carefully controlled during transport of patients outside ICU
- Oral care with chlorhexidine
- Avoid stress ulcer prophylaxis in very low-risk patients for gastrointestinal bleed, and consider use of sucralfate when indicated.
- Semirecumbent patient positioning
- Continuous lateral rotation therapy
- Postpyloric feeding in patients who have impaired gastric emptying
- SDD for patients requiring >48 hours of mechanical ventilation

ICU, intensive care unit; NIV, noninvasive ventilation; PEEP, positive end-expiratory pressure; SDD, selective digestive decontamination.

laboratory and clinical trials. In particular, the polyurethane cuff has a thickness of 5 to 10 μm , in comparison to 50 μm for PVC cuffs. Hence, upon inflation, smaller folds form with polyurethane cuffs, and aspiration of secretions above the cuff can be prevented or reduced. Some investigators have attempted to prevent aspiration by modifying the shape of the cuff.¹⁶¹ In comparison to standard cuffs with cylindrical shapes, cuffs designed with a smooth, tapering shape allow elimination of folds for a full circumference of the trachea or cuff contact zone, irrespective of the cuff material.

A few studies in medical ICU patients have shown that polyurethane cuffs reduce risks of developing VAP.^{162,163} The polyurethane-cuffed ETT has also shown benefits in reducing early postoperative pneumonia in cardiac surgical patients.^{164,165} Interestingly, in a recent multicenter study,¹⁶⁶ cuffs composed of cylindrical polyvinyl chloride, cylindrical polyurethane, conical polyvinyl chloride, or conical polyurethane were compared in the prevention of VAP, and no benefits were found with the use of polyurethane or conical cuffs. Silicone¹⁵⁹ and latex¹⁶⁰ cuffs are low volume and low pressure and are potential alternatives to PVC cuffs since folds are never formed upon inflation within the trachea. In a clinical trial on patients undergoing anesthesia or admitted to the ICU, Young et al.¹⁵⁹ demonstrated high effectiveness of a silicone cuff in reducing pulmonary aspiration. In our opinion, due to the lack of clear evidence on the benefits of these new cuffs, their use should be only limited to patients at very high risk of developing VAP.

It is important to maintain the internal ETT cuff pressure between 25 and 30 cm H₂O to prevent aspiration of contaminated secretions into the lower airways and tracheal injury. Several studies¹⁶⁷⁻¹⁶⁹ have demonstrated that frequently the ETT cuff was underinflated or hyperinflated using standard management. Continuous control of internal cuff pressure reduces risks of significant deflation and pulmonary aspiration.

Ventilatory settings may play a role in the pathogenesis of VAP. In particular, PEEP may decrease the incidence of VAP by counteracting hydrostatic pressure exerted by oropharyngeal secretions above the ETT cuff, hence reducing pulmonary aspiration.^{170,171} Lucangelo et al.¹⁷² assessed the effects of 5 to 8 cm H₂O PEEP in normoxemic ventilated patients and showed a reduction in the rate of VAP. Thus, in the absence of major contraindications, a low level of PEEP should be maintained to avoid pulmonary aspiration.

Tracheal Tubes Coated with Antimicrobial Agents

Coating the ETT with antimicrobial agents, such as silver, is a promising strategy to prevent biofilm formation on its internal surface and VAP.¹⁷³ Olson et al.¹⁷⁴ tested a silver-coated ETT in dogs challenged with *P. aeruginosa* into the oropharynx. Using the new tube, the investigators were able to postpone colonization of the ETT inner surface and reduce pulmonary bacterial burden. Similarly, Berra et al.¹⁷⁵ studied a silver sulfadiazine/chlorhexidine-coated ETT in sheep. After 24 hours of MV, standard ETTs and ventilatory circuits were heavily colonized, whereas the novel coated ETT fully avoided colonization. Interestingly, the efficacy of silver-based coatings seems to decrease over time. Indeed, animal studies reported heavy colonization of silver-coated ETTs after 72 hours of MV. To date, only one laboratory study¹⁷⁶ has shown the absence of ETT biofilm formation up to 168 hours of MV, when silver sulfadiazine ETTs were regularly cleaned with the Mucus Shaver.¹⁷⁷ The North American Silver-Coated Endotracheal Tube (NASCENT) randomized trial¹⁷⁸ compared the preventive effects of a silver-coated vs. conventional ETT. The silver-coated ETT was associated with a lower incidence of microbiologically confirmed VAP (4.8% vs. 7.5%; $P = 0.03$), for a relative risk reduction of 35.9%. A retrospective cohort analysis by Afessa et al.¹⁷⁹ showed that the silver-coated ETT was associated with reduced mortality in patients with VAP (14% vs. 36% in silver and control ETT, respectively, $P = 0.03$). Mortality was higher in those without VAP. In conclusion, ETT coated with antimicrobial agents could reduce the incidence of VAP, but the

evidence supporting its use comes only from one study, with significant limitations.¹⁸⁰ Thus, clinicians should carefully consider benefits and limitations of these ETTs and properly direct the use of silver-coated tubes to patients expected to be ventilated for longer periods of time and with higher risks for nosocomial pneumonia. Shorr et al.¹⁸¹ analyzed the cost-effectiveness of the silver-coated ETT and found that per each prevented VAP, US\$12,840 was saved.

Aspiration of Subglottic Secretions

Aspiration of colonized subglottic secretions through dedicated ETTs reduces hydrostatic pressure exerted above the cuff and potentially prevents leakage across the cuff. A meta-analysis¹⁸² has shown that drainage of subglottic secretions reduced the overall risk ratio (RR) for VAP by half (RR, 0.55; 95% CI, 0.46-0.66; $P < 0.01$). In a multicenter trial by Lacherade et al.,¹⁸³ 333 patients were randomized to be intubated with either an ETT that allowed drainage of subglottic secretions or a standard ETT. Microbiologically confirmed VAP occurred in 14.8% of the patients in the treatment group, compared to 25.6% of the patients intubated with a standard tube ($P = 0.02$). Interestingly, subglottic secretion drainage has been consistently associated with tracheal injury in clinical¹⁸⁴ and laboratory studies.^{24,185}

Tracheostomy

Tracheostomized patients present the same risks for aspiration of pathogen-laden secretions pooled above the cuff as orotracheally intubated patients. In the most recent meta-analysis¹⁸⁶ that assessed outcomes of early versus late tracheostomy, early tracheostomy did not reduce the incidence of VAP. Early tracheostomy may improve patient comfort, ability to communicate, capability for oral feeding, reduce the need for sedation and analgesia, and reduce airway resistance in comparison to standard ETTs. These factors are of paramount importance during the weaning period to shorten the duration of tracheal intubation.

Ventilator Circuit Management

Clinical trials in adults¹⁸⁷⁻¹⁹² and meta-analyses¹⁹³ have demonstrated that a routine change of the ventilator circuit does not decrease risks for VAP or costs. Therefore, circuits should not be changed unless the circuit is soiled or damaged. Importantly, inadvertent flushing of the contaminated condensate into the lower airways or nebulizers should always be avoided by careful emptying of ventilator circuits and water traps.^{194,195}

The latest meta-analysis¹⁹⁶ that assessed the effects of heated humidifiers (HH) and heat and moisture exchangers (HME) on prevention of nosocomial pneumonia showed no effect on pneumonia prevention. To date, neither humidification strategy can be recommended as a pneumonia prevention tool. However, it is rational to deliver inspiratory gases at body temperature or slightly below and at the highest relative humidity to prevent loss of heat and moisture from the airways, change in rheologic properties of secretions, and impairment of mucociliary clearance. Therefore, the use of HH is particularly indicated in patients with hypothermia, prolonged MV, thick secretions, and chronic respiratory disorders. Finally, studies¹⁹⁷⁻²⁰¹ testing less frequent changes of HMEs have not found increased risks for VAP. HMEs should be changed periodically (i.e., every 72 hours), to ensure good performance.

Closed tracheal suctioning systems have been introduced in clinical settings to avoid adverse events associated with ventilator disconnection during open tracheal suctioning and exogenous contamination of suction catheters entering the ETT. Three meta-analyses²⁰²⁻²⁰⁴ have compared the closed to the open tracheal suction system in mechanically ventilated patients and found no benefits of VAP prevention.

The use of a saline solution instilled into the ETT before tracheal suctioning remains controversial. A systematic review²⁰⁵ consistently

found a decrease in patient oxygenation in most studies. Only one study²⁰⁶ found a lower incidence of microbiologically proven VAP (saline instillation versus no treatment: 23.5% vs. 10.8%; $P = 0.008$). Importantly, in sedated patients in the semirecumbent position and with the ETT internal surface highly colonized, saline instillation may increase risks for translocation of pathogens into the airways.

Body Position

Early studies demonstrated that intubated patients are at higher risk for gastropulmonary aspiration when placed in the supine position (0 degrees) as compared with a semirecumbent position (45 degrees).^{73,207,208} One randomized trial²⁰⁹ demonstrated a reduction in the incidence of VAP in patients positioned in the semirecumbent position compared with patients completely supine, particularly during enteral feeding. A later randomized trial²¹⁰ found limited feasibility of the intervention and no differences in VAP incidence. Thus, as strongly suggested by the American¹ and European guidelines,²¹¹ intubated patients should be preferentially kept in the semirecumbent position (30-45 degrees) rather than supine (0 degrees), especially when receiving enteral feeding.

Laboratory reports^{212,213} have challenged the preventive benefits of the semirecumbent position. Theoretically, in tracheally intubated patients a tracheal orientation above horizontal might facilitate aspiration across the ETT cuff. Conversely, laboratory studies^{213,214} consistently found that the lateral-Trendelenburg position enhances mucous drainage and decreases risks for VAP. Currently, a multicenter clinical trial is testing in critically ill patients the efficacy, safety, and feasibility of the lateral-Trendelenburg position in the prevention of VAP (available from ClinicalTrials.gov; NLM Identifier: NCT01138540).

Rotating Bed

Several ICU beds permit the rotation of patients in the longitudinal axis from one lateral position to the other and reduce extravascular lung water, improve the ventilation-perfusion ratio, and enhance mobilization of airway secretions.²¹⁵ Meta-analyses²¹⁶⁻²¹⁸ have shown a significant reduction in the incidence of VAP in patients undergoing rotation therapy. Staudinger et al.²¹⁹ studied the effects of continuous lateral rotation therapy and found a VAP incidence of 11% in the rotation group and 23% in the control group ($P = 0.048$). The authors also found that the duration of ventilation (8 ± 5 vs. 14 ± 23 days; $P = 0.02$) and length of stay (25 ± 22 days vs. 39 ± 45 days; $P = 0.01$) were significantly shorter in the rotational group. In conclusion, in patients at a higher risk for prolonged immobilization and respiratory infection, continuous lateral rotation therapy should be considered for exerting additive effects to other preventive measures for VAP.

Stress Ulcer Prophylaxis and Enteral Feeding

Sucralfate, histamine type 2 blockers (H_2 blockers), or proton pump inhibitors (PPIs) are the most common medication for stress ulcer prophylaxis. Sucralfate is the only treatment that does not cause gastric alkalization. Early studies found a higher incidence of pneumonia in patients with alkalized gastric contents,⁷⁶⁻⁷⁸ whereas others have not.^{80,220} Cook et al.²²⁰ found a higher risk of GI bleeding using sucralfate and no significant difference in VAP incidence: 19.1% and 16.2% in patients treated with H_2 blockers or sucralfate, respectively. Likewise, in a recent meta-analysis,²²¹ PPIs were more effective than H_2 blockers at reducing upper gastrointestinal bleeding, without differences in VAP (relative risk = 1.06; 95% CI = 0.73-1.52; $P = 0.76$). In conclusion, GI bleeding is a serious complication in critically ill patients. The actual risk for VAP is unknown when accurate methods of enteral feeding (i.e., avoiding large gastric residual volumes) or other preventive measures are used in combination with stress ulcer prophylaxis. Therefore, clinicians must weigh the potential benefit of sucralfate (with potentially less VAP and more GI bleeding) versus H_2 blockers/PPI (with potentially more VAP and less GI

bleeding) and probably limit stress ulcer prophylaxis to high-risk patients.

Enteral nutrition has been considered a risk factor for the development of VAP, because of increased risks for gastric alkalization, gastroesophageal reflux, and gastropulmonary aspiration. However, its alternative, parenteral nutrition, is associated with higher risks for catheter-related infections, complications of line insertions, higher costs, and loss of intestinal villous architecture, which may facilitate enteral microbial translocation. A large meta-analysis²²² of 11 studies comprising more than 500 critically ill patients found that the use of parenteral nutrition was associated with more infectious complications, compared to early enteral nutrition (OR = 1.47; 95% CI = 0.90-2.38; $P = 0.12$). Conversely, studies in medical ICU patients have demonstrated a higher risk for VAP with early enteral feeding.^{223,224} Therefore, in medical ICU patients, the benefits of early nutrition should be balanced with associated increased risks for VAP.

Many ICU patients present impaired gastric emptying; hence, the placement of the feeding tube beyond the pylorus has the potential to achieve nutrition goals without increased risks for gastropulmonary aspiration. The most recent meta-analysis by Jiyong et al.²²⁵ found that small bowel feedings were associated with a lower incidence of pneumonia (RR = 0.63; 95% CI = 0.48-0.83; $P = 0.001$). In an interesting report by Davies and collaborators,²²⁶ in mechanically ventilated patients with mildly elevated gastric residual volumes and already receiving nasogastric nutrition, early postpyloric nutrition did not increase energy delivery or reduce the frequency of pneumonia. Therefore, postpyloric feeding should be preferred only when impaired gastric emptying is present. Finally, a recent study²²⁷ challenged the utility of routine monitoring of residual gastric volume in 449 patients receiving invasive MV and early enteral nutrition. VAP occurred in 16.7% of the patients without routine monitoring, in comparison with 15.8% in the control group.

Modulation of Oropharyngeal and Gastrointestinal Colonization

Given the pivotal role of oropharyngeal colonization in the development of VAP,⁴¹ many decontamination strategies have been developed, which include hand washing, oral hygiene and tooth brushing,²²⁸ selective oral decontamination with topical nonabsorbable antibiotics,²²⁹ and oropharyngeal rinsing with antiseptics.²³⁰ Chlorhexidine is a cationic chlorophenyl bis-biguanide antiseptic that has long been used as an inhibitor of dental plaque formation and gingivitis. A meta-analysis²³⁰ of studies assessing the benefits of chlorhexidine on the reduction of VAP reported fewer lower respiratory tract infections in cardiac surgery patients (RR = 0.56; 95% CI = 0.41-0.77) without a significant mortality difference (RR = 0.88; 95% CI = 0.25-2.14). Results in noncardiac ICU populations are inconsistent. Most of the studies described earlier used chlorhexidine concentrations up to 0.2%. This concentration may not be effective in most ICU patients with high levels of oropharyngeal colonization. Studies^{231,232} have demonstrated significant reductions in VAP rates when chlorhexidine concentration was increased to 2%. Therefore, oral decontamination with chlorhexidine should be routinely used, specifically in cardiothoracic patients. In other ICU populations, the use of higher chlorhexidine concentrations could be a promising option. Alternatively, some investigators recently tested once-daily bathing of all patients with disposable cloths impregnated with 2% chlorhexidine as a preemptive strategy for nosocomial infections, but they did not find any significant benefit with this approach.²³³

Selective digestive decontamination (SDD) comprises a combination of nonabsorbable antibiotics against gram-negative pathogens (i.e., tobramycin and polymyxin E), plus either amphotericin B or nystatin. These agents are administered into the GI tract to prevent oropharyngeal and gastric colonization with aerobic Gram-negative bacilli and *Candida* spp. while preserving the anaerobic flora. Some regimens include a short course of systemic antibiotics (i.e., cefotaxime). SDD was originally applied to oncologic and hematologic

patients with severe immunosuppression.^{234,235} In the early 1980s, Stoutenbeek introduced this practice into critical care medicine.²³⁶ Since then, a remarkable number of clinical trials and meta-analyses confirmed the benefits associated with the use of SDD, which was associated with a reduction in the incidence of VAP, bacterial bloodstream infections, and mortality.²³⁷ Currently, SDD is primarily applied in European centers with low levels of MDR.²³⁸

Randomized clinical trials^{229,239,240} and meta-analyses²³⁷ confirmed that SDD confers protection against nosocomial pneumonia. Several factors should be taken into account before extending its use worldwide. First, the most recent investigations on the intestinal microbiota highlight the variability, interactions, and complexity of gastrointestinal bacterial colonies, and systemic consequences of changes in gut colonization.²⁴¹⁻²⁴⁷ Indeed, it is known that more than 10^{11} bacteria per gram of feces, comprising more than 1000 different species, are present in our intestinal system.²⁴⁸ Large interindividual variations in bacterial patterns are evident even among humans living in the same geographic region.²⁴⁹ With the advent of individualized medicine, the use of a unit-wide single SDD regimen for all ICU population subtypes²⁵⁰ seems farfetched. In addition, even the selectivity of SDD against aerobic Gram-negative bacteria has been challenged.²⁵¹ Thus, the impact of SDD on the intestinal microbiota and the resulting alterations of bacterial diversity need further evaluation. Second, one of the most recurrent arguments for not using SDD is that microorganisms not addressed by the regimen may be selected (i.e., MRSA and *Enterococcus* spp.) or MDR for the applied antibiotics may increase. A recent study²⁵² demonstrated an increase in anaerobic flora antibiotic resistance genes during SDD, particularly highly transferable genes conferring resistance to aminoglycosides. In line with these results, Oostdijk and collaborators²³⁹ found increases in aminoglycoside-resistant Gram-negative bacteria during SDD use. Finally, in one older study²⁵³ by the same group that explored recolonization following SDD, increased intestinal colonization with Gram-negative bacteria resistant to ceftazidime, tobramycin, or ciprofloxacin was found. Likewise, resistance to ceftazidime increased gradually in the respiratory tract during SDD and even further post intervention, for all three antibiotics. This suggests that there are still several unknown effects of SDD that need to be addressed. An ongoing European trial is addressing these questions. The R-GNOSIS (Resistance in Gram-Negative Organisms: Studying Intervention Strategies) is evaluating the most effective measures to reduce infections caused by MDR pathogens and to understand the ecologic effects of decolonization strategies in patients admitted to the ICU (available from <https://www.clinicaltrials.gov/ct2/show/NCT02208154?term=bonten&rank=2>).

Only one study²⁵⁴ has demonstrated that a short course of cefuroxime in patients with structural coma or severe burns was an effective prophylactic strategy to decrease the VAP rate. However, routine use of parenteral antibiotics is not recommended until more data become available.

Several clinical trials have attempted to modify GI and oropharyngeal growth of pathogens through the use of probiotics. Probiotics are microorganisms that can be administered either as individual strains or in various combinations. These microorganisms are often administered with nondigestible food ingredients that facilitate bacterial growth and activity (prebiotics). Products containing both probiotics and prebiotics are called *synbiotics*. The latest meta-analysis²⁵⁵ on the effects of probiotics suggests that probiotics may reduce the incidence of VAP. The quality of the evidence is low and is lacking to draw firm conclusions on this subject.

DIAGNOSIS

The diagnosis of VAP is a controversial issue.²⁵⁶⁻²⁵⁸ Clinical signs suggestive of pneumonia, such as fever, tachycardia, and leukocytosis, are nonspecific in critically ill patients.^{259,260} Moreover, particularly in ventilated patients with bronchiectasis and/or COPD, the chest radiograph is difficult to interpret, and it may not reveal subtle lung infiltrates, which are only detected by computed tomography (CT) scans.²⁶¹

TABLE 75-1 The Clinical Pulmonary Infection Score (CPIS)

| CRITERION | 0 | 1 | 2 |
|------------------------------------|-------------------|------------------|--|
| Tracheal secretions | Absent | Not purulent | Abundant and purulent |
| Chest x-ray infiltrates | No | Diffuse | Localized |
| Temperature, °C | ≥36.5 and ≤38.4 | ≥38.5 or ≤38.9 | ≥39 or ≤36 |
| Leukocytes | ≥4000 and ≤11,000 | <4000 or >11,000 | <4000 or >11,000 + immature neutrophils >50% or >500 |
| PaO ₂ /FiO ₂ | >240 or ARDS | | ≤240, no ARDS |
| Microbiology | Negative | | Positive |

Data from Pugin J, Auckenthaler R, Mili N, et al. Diagnosis of ventilator-associated pneumonia by bacteriologic analysis of bronchoscopic and non-bronchoscopic "blind" bronchoalveolar lavage fluid. *Am Rev Respir Dis* 1991;143:1121-9.

CPIS is considered positive with a score ≥6.

ARDS, acute respiratory distress syndrome.

When infiltrates are evident, the differential diagnosis is challenging (i.e., cardiogenic and noncardiogenic pulmonary edema, pulmonary contusion, and atelectasis).

Few studies have examined the accuracy of portable chest radiographs in the diagnosis of VAP.²⁶²⁻²⁶⁵ In mechanically ventilated patients with autopsy-proven VAP, no single radiographic sign had a diagnostic accuracy greater than 68%.²⁶⁵ In patients with ARDS, marked heterogeneity of radiographic abnormalities has been reported.²⁶⁶ A clinical study showed the presence of lung infection in only 42% of the patients with clinically suspected VAP.²⁶⁷ The presence of air bronchograms may increase the specificity of chest radiographs in ARDS patients.

The Clinical Pulmonary Infection Score (CPIS) is based on six clinical assessments (Table 75-1).²⁶⁸ The CPIS showed a good correlation ($r = 0.84$; $P < 0.0001$) with quantitative bacteriology of BAL samples. Moreover, a value ≥6 was the threshold to accurately identify patients with pneumonia. The value of CPIS remains to be validated in a large prospective study, especially in patients with bilateral pulmonary infiltrates.

The presence of bacteria in the lower airways of intubated patients is not sufficient to diagnose VAP, because it could be only nonpathogenic colonization or VAT.^{41,269} Cultures of endotracheal aspirate from patients with respiratory failure and histologically documented pneumonia, simultaneously obtained from the trachea and lung tissue, agreed in only 40% of cases, with a 82% sensitivity and 27% specificity.²⁷⁰ Similarly, in another study, only 23% of colonized patients subsequently developed VAP.⁴¹

Many sampling procedures of respiratory secretions, such as sputum collection, endotracheal aspirates, BAL, and PSB, are available. In addition, there are several microbiological techniques, including Gram staining and intracellular organism count, for specimens obtained via BAL. Each diagnostic technique has advantages as well as limitations and provides different diagnostic specificity and sensitivity.

Qualitative cultures of endotracheal aspirates have a high percentage of false-positive results. Conversely, quantitative culture techniques are more reliable if appropriate cutoff criteria are applied. When patients develop pneumonia, pathogens are present in the lower respiratory tract secretions at concentrations of at least 10^5 to 10^6 CFU/mL.²⁷¹⁻²⁷⁴ The current diagnostic threshold proposed for tracheal aspirates is 10^6 CFU/mL. Similarly, PSB collects between 0.001 and 0.01 mL of secretions. Therefore, the presence of more than 10^3 bacteria in the originally diluted sample (1 mL) represents 10^5 to 10^6 CFU/mL in

pulmonary secretions. Finally, 10^4 CFU/mL is considered the cutoff for BAL, which collects 1 mL of secretions in 10 to 100 mL of effluent.

In one study,²⁷⁴ only 40% of the microorganisms cultured in endotracheal aspirate samples coincided with those obtained from PSB specimens. Also, when quantitative cultures of different lower respiratory tract specimens were compared with postmortem quantitative lung biopsy cultures, all techniques for detecting VAP were of limited value.²⁷⁵

A major problem in the management of patients with suspicion of VAP is the use of antibiotics. The indiscriminate administration of antimicrobial agents for patients in the ICU may contribute to the emergence of MDR pathogens and increase the risk of superinfections with increased morbidity and mortality, as well as expose the patient to antibiotic-related adverse effects and higher costs.²⁷⁶ On the other hand, correct and prompt treatment of pneumonia results in better patient survival.²⁷⁷⁻²⁸⁰ Inadequate empirical antibiotic treatment, initiated before obtaining the results of cultures from respiratory secretions was associated with greater hospital mortality compared with antibiotic regimens that provided adequate antimicrobial coverage based on microbiological culture results.²⁸¹⁻²⁸⁵ However, the choice of initial antibiotic treatment is often difficult due to previous antibiotic treatment,²⁸⁶ prevalence of MDR pathogens,⁷ and colonizing pathogens.²⁸⁷⁻²⁸⁹

Recently, several alternative techniques to perform microbial cultures have been developed that achieve a more rapid and accurate diagnosis of nosocomial pneumonia (i.e., high multiplexing real-time polymerase chain reaction arrays²⁹⁰ and fluorescent in situ hybridization of bacteria).²⁹¹ These methods proved to be feasible for rapidly detecting causative pathogens. Additionally, efforts have been made to detect rapidly the most important MDR genes, such as *mecA*, *blaKPC*, *blaIMP*, *blaVIM*, and *blaOXA*.²⁹² Finally, a Spanish study tested a rapid E-test antibiogram for six antibiotic agents that could provide antibiotic susceptibility within 24 hours and found that the use of this technique resulted in more appropriate and reduced use of antibiotics in VAP patients.²⁹³

Ventilator-Associated Events Surveillance Algorithm

The Centers for Disease Control introduced the ventilator-associated events (VAE) surveillance definition algorithm²⁹⁴ to monitor complications in mechanically ventilated patients (Fig. 75-2). This new algorithm was developed to monitor objectively pulmonary complications associated with worse outcomes in mechanically ventilated patients. Importantly, reports demonstrated poor concordance between infection-related ventilator-associated condition (IVAC), possible and probable VAP, and VAP diagnosed with standard criteria.^{295,296} In a study by Boudma and collaborators,²⁹⁷ sensitivity and specificity of diagnosing VAP were 0.92 and 0.28 for the ventilator-associated condition, and 0.67 and 0.75 for infection-related ventilator-associated complication, respectively. Boyer et al.²⁹⁸ studied 1209 patients ventilated for ≥ 2 calendar days with 5.5% VAE. The most common causes of VACs included IVACs (50.7%), ARDS (16.4%), pulmonary edema (14.9%), and atelectasis (9.0%). The sensitivity of the VAE algorithm for the detection of VAP was only 25.9% (95% CI = 16.7%-34.5%). Thus, the VAE algorithm should be considered as a powerful benchmarking tool but with marginal value for the diagnosis of VAP.

Diagnostic Strategies for Hospital-Acquired Pneumonia

An ideal diagnostic strategy for patients with clinical suspicion of hospital-acquired pneumonia should reach the following objectives:

1. Accurately identify patients with true pulmonary infection and isolate the causative microorganisms to initiate promptly appropriate antimicrobial treatment and subsequently to optimize therapy based on the susceptibility of the pathogens.
2. Identify patients with extrapulmonary sites of infection.
3. Withhold and/or withdraw antibiotics in patients without infection.

The diagnosis of nosocomial pneumonia begins with clinical suspicion. The presence of a new or progressive radiographic infiltrates plus at least two of three clinical criteria (fever/hypothermia, leukocytosis/leukopenia, and purulent secretions) represents the starting point to begin diagnostic procedures.

Two diagnostic algorithms can be used when there is clinical suspicion of nosocomial pneumonia. The clinical approach recommends treating every patient with suspicion of having a pulmonary infection with new antibiotics even when the likelihood of infection is low (Fig. 75-3). However, samples of respiratory secretions (e.g., endotracheal aspirate or sputum) should be obtained before the initiation of antibiotic treatment. In this strategy, the selection of an appropriate empirical therapy is based on risk factors and local resistance patterns. The etiology of pneumonia is defined by semiquantitative cultures of endotracheal aspirates or sputum, with an initial microscopic examination of the Gram stain. Antimicrobial therapy is adjusted according to culture results or the clinical response. The semiquantitative culture of tracheal aspirates has the advantage that no specialized microbiological techniques are required and the sensitivity is high. This clinical strategy provides antimicrobial treatment to the majority of the patients with suspicion of HAP and yields a low rate of false negatives. If the tracheal aspirate culture does not demonstrate pathogens and the patient has not received new antibiotics within the previous 72 hours, the diagnosis of pneumonia is unlikely.²⁸⁵ This strategy is useful in centers where bronchoscopic methods are not always available. The main drawback of this strategy is that the high sensitivity of semiquantitative cultures of tracheal aspirates leads to an overestimation of the incidence of HAP and overuse of antibiotics.

The bacteriologic strategy is based on the results of quantitative cultures of lower respiratory secretions (Fig. 75-4). The procedure used to collect the samples (endotracheal aspirate, BAL, or PSB) may be invasive (bronchoscopic) or noninvasive (blind procedures). The bacteriologic strategy attempts to identify accurately patients with true HAP so that only infected patients are treated and clinical outcomes are improved.^{283,289} Such a strategy reduces the risks for overuse of antibiotics, since quantitative cultures yield fewer microorganisms above the threshold, in comparison to semiquantitative cultures. Among the disadvantages of the bacteriologic strategy is the possibility of obtaining false-negative results that lead to delayed antibiotic treatment in a patient with pneumonia. Moreover, results using the bacteriologic strategy may lack reproducibility, and often no microbiological information is available at the time of initiation of empirical antibiotic therapy.

Four randomized controlled trials (RCTs)^{283,299-301} have assessed the impact of diagnostic strategies on antibiotic use and outcome in patients with clinically suspected VAP. In three small studies,^{283,299,300} invasive diagnostic techniques resulted in a greater number of antibiotic changes than noninvasive techniques; however, no differences in mortality and morbidity were found when either invasive (PSB and/or BAL) or noninvasive (quantitative endotracheal aspirate cultures) techniques were used. By contrast, a larger trial³⁰¹ showed a reduction in mortality, reduced use of antibiotics, and increased number of antibiotic-free days using invasive diagnostic techniques. This study was limited, however, by the use of qualitative cultures of tracheal aspirates, thereby limiting comparison with other clinical trials. Irrespective of the methods used to obtain respiratory samples, it is strongly recommended that samples be obtained before starting new antibiotics, or a lower threshold should be used in patients with recent antibiotic changes.^{302,303}

A clinical trial³⁰⁴ compared the quantitative culture of BAL fluid and culture of endotracheal aspirate in critically ill patients with suspected VAP. This study was part of a larger 2-by-2 factorial design also comparing empirical antimicrobial monotherapy (a carbapenem) and combination therapy (a carbapenem plus a fluoroquinolone). A total of 740 patients in 28 ICUs throughout Canada and the United States were enrolled, and the authors found no difference in the 28-day mortality rate between the BAL group and the endotracheal aspiration group (18.9% and 18.4%, respectively; $P = 0.94$). The BAL group and

the endotracheal aspiration group also had similar rates of targeted therapy and days alive without antibiotics. At least 40% of the screened patients were excluded because they were at risk for colonization with *Pseudomonas* spp. or MRSA or were immunosuppressed. Therefore, translation of these findings into clinical practice is challenging, because many ICU patients evaluated for suspected VAP fall into these categories. Last, in the latest meta-analysis,³⁰⁵ no differences using quantitative cultures versus qualitative cultures in mortality rates (RR = 0.91; 95% CI = 0.75 to 1.11), the number of days on MV, the length of ICU stay, or antibiotic changes were found. Likewise, there was no effect of invasive versus noninvasive diagnostic methods.

Practical Implementation of a Diagnostic Strategy in Suspected VAP

In clinical practice, the development of local clinical guidelines can combine both clinical and bacteriologic strategies (Table 75-2). The diagnostic protocol begins with clinical suspicion of a nosocomial

TABLE 75-2

Diagnostic Protocol to Combine Clinical and Bacteriologic Strategies for the Diagnosis of Ventilator-Associated Pneumonia

1. As soon as pneumonia or infection associated with mechanical ventilation is suspected and before initiating new empirical antibiotic treatment, collect samples as follows*:
 - Expectoration
 - Tracheobronchial aspirate (BAS)**
 - Bronchoalveolar lavage (BAL) or mini-BAL**
 - Protected brush specimen (PBS)**
2. Two blood cultures
3. In cases of evidence for parapneumonic effusion, obtain pleural fluid sample
4. Obtain *Legionella pneumophila* and *Streptococcus pneumoniae* antigens in urine
5. Other lab tests: complete blood cell count, serum electrolytes, liver and renal function tests, C-reactive protein, procalcitonin, arterial blood gases

*Samples should be sent to the microbiology department or, if not available, maintained in the refrigerator at 4°C (only respiratory samples) for a maximum of 1 hour for Gram staining, intracellular organism counting (only in BAL and mini-BAL), and quantitative cultures. The collection of lower respiratory secretion samples should not delay the initiation of empirical treatment in patients with severe sepsis.

**These techniques may be performed by bronchoscopy or blind procedures. Quantitative cultures are performed with the respiratory secretions obtained by BAS, BAL, or PBS. The cutoff count to diagnose pneumonia is the following: BAS 10⁶ CFU/mL, BAL 10⁴ CFU/mL, and PBS 10³ CFU/mL.

respiratory infection (Fig. 75-5). In mechanically ventilated patients, the presence of an infiltrate on chest radiograph differentiates between the possible presence of pneumonia and tracheobronchitis. The next step is to sample the lower respiratory tract (see Table 75-3) to identify the causative microorganism. Respiratory tract specimens can be obtained by expectoration, bronchial aspirate, BAL, or PSB. The latter two techniques can be performed with bronchoscopy or blindly. Several other samples should also be collected, as noted in Table 75-2. With clinical suspicion of pneumonia, CPIS²⁶⁸ should be calculated to improve the objective assessment of the clinical parameters (Table 75-1).

TREATMENT

Once the clinical decision to initiate antimicrobial therapy has been made, the following issues should be considered to achieve the best antimicrobial efficacy and reduce overuse of antibiotics:

- The most likely etiologic microorganisms
- Choice of the empirical antimicrobials likely to be active against these microorganisms
- Adjustment of therapy following microbiologic results and duration of treatment

Likely Etiologic Microorganisms

As detailed in previous paragraphs, microorganisms causing VAP originate from the oropharyngeal flora of the patient. Underlying chronic diseases, specific risk factors, acute inflammatory processes, and factors specific to each hospital or ICU can facilitate abnormal bacterial colonization of the oropharynx and may predispose patients to infection with specific organisms. Therefore, the selection of initial antimicrobial therapy must be tailored to the local prevalence of pathogens and antimicrobial patterns of resistance at each institution.¹⁰⁷ The dynamics of change of oropharyngeal flora during hospital stay can be described as follows (Fig. 75-6):

1. Healthy subjects are colonized with normal oropharyngeal flora in which pathogenic microorganisms, such as *S. pneumoniae*, group A streptococci, or meningococci may be transiently found.
2. Patients with chronic comorbidities or an acute inflammatory process have impairment of normal immune responses. As a result, *S. aureus* and Enterobacteriaceae can colonize the oropharynx.
3. Patients who have received antibiotic treatment become colonized with resistant pathogens, including ESBL + Enterobacteriaceae, *Enterobacter* spp., *P. aeruginosa*, or MRSA.

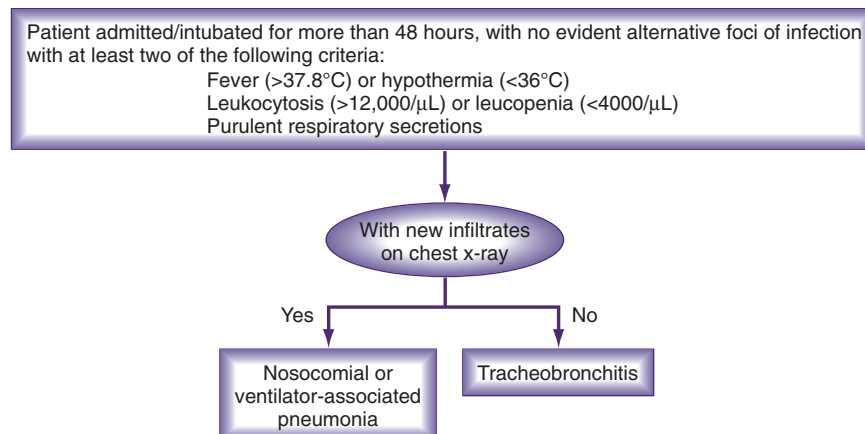

FIGURE 75-5 ■ Clinical suspicion of nosocomial respiratory infection.

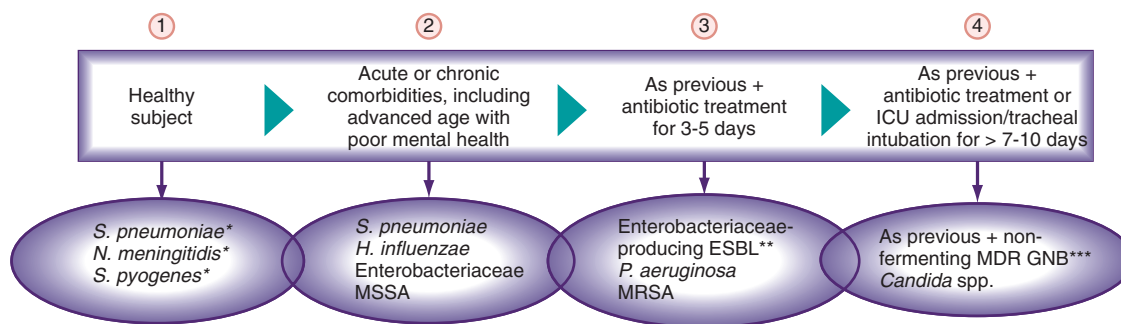

FIGURE 75-6 ■ Evolution of potentially pathogenic microorganisms present in oropharyngeal flora, related to comorbidity, antibiotic treatment, and colonization pressure. *Transitorily present in healthy carriers. **Producers of ESBL or with type ampC chromosomal β -lactamases. ****Pseudomonas aeruginosa*, *Stenotrophomonas* spp., *Acinetobacter* spp., *Burkholderia* spp. ESBL, extended-spectrum β -lactamase; GNB, gram-negative bacilli; MDR, multidrug resistant; MRSA, methicillin-resistant *Staphylococcus aureus*; MSSA, methicillin-sensitive *S. aureus*.

4. Patients who have received broad-spectrum antibiotics for more than 7 days are often colonized by MDR microorganisms (i.e., *A. baumannii*, *S. maltophilia*, *B. cepacia*, and gram-positive microorganisms).

Changes in the oropharyngeal flora tend to occur progressively such that the presence of microorganisms during one stage often overlaps with the next stage.

Choice of Empirical Antimicrobials Likely to Be Active Against Causative Microorganisms

The latest guidelines of the American Thoracic Society and Infectious Diseases Society of America (ATS/IDSA) for the management of adult patients with nosocomial pneumonia recommend¹ that the selection of empirical antibiotic therapy for each patient should be based on the timing of onset and presence of risk factors for MDR pathogens. Risk factors for MDR pathogens defined by the ATS/IDSA guidelines are summarized in **Box 75-2**. An algorithm for the initial management of patients with nosocomial respiratory infection and selection of appropriate antimicrobials is shown in **Fig. 75-7**. The antibiotics recommended by the latest ATS/IDSA guidelines are shown in **Tables 75-3** and **75-4**. Adequate dosing of antibiotics for empirical therapy is summarized in **Table 75-5**. Broad-spectrum empirical antibiotic therapy should be rapidly deescalated as soon as microbiological data become available to limit the emergence of resistance in the hospital. **Fig. 75-7**, **Table 75-3**, and **Table 75-4** detail empirical therapy, which should be based on patient's risk of colonization by MDR organisms.

As for the need for dual therapy against Gram-negative pathogens, in a meta-analysis by Aarts et al.,³⁰⁶ 11 trials randomizing 1805 patients were evaluated. There was no mortality difference for patients receiving monotherapy versus combination therapy (RR = 0.94, 0.76-1.16). Likewise, there was no significant difference in treatment failure in patients with clinically suspected pneumonia (RR = 0.88, 0.72-1.07; **Fig. 75-5**) or microbiologically proven pneumonia (RR = 0.86, 0.63-1.16).

Nebulized Antibiotics

Intravenous administration of antibiotics for nosocomial pneumonia has several limitations, including insufficient lung distribution, development of adverse side effects, and selective pressure for development of MDR. Additionally, intravenous antibiotics are often underdosed in critically ill patients, due to sepsis-related higher volumes of distribution and hyperdynamic states. Administration of nebulized antibiotics is a potential therapeutic alternative^{307,308} to overcome these limitations. Additionally, systemic exposure to antibiotics and potential adverse

BOX 75-2

Risk Factors for Multidrug-Resistant Pathogens Causing Nosocomial Pneumonia

- Antimicrobial therapy in preceding 90 days
- Current hospitalization of 5 days or more
- High frequency of antibiotic resistance in the community or in the specific hospital unit
- Presence of risk factors for healthcare-associated pneumonia:
 - Hospitalization for 2 days or more in the preceding 90 days
 - Residence in a nursing home or extended care facility
 - Home infusion therapy (including antibiotics)
 - Chronic dialysis within 30 days
 - Home wound care
 - Family member with multidrug-resistant pathogen
- Immunosuppressive disease and/or therapy

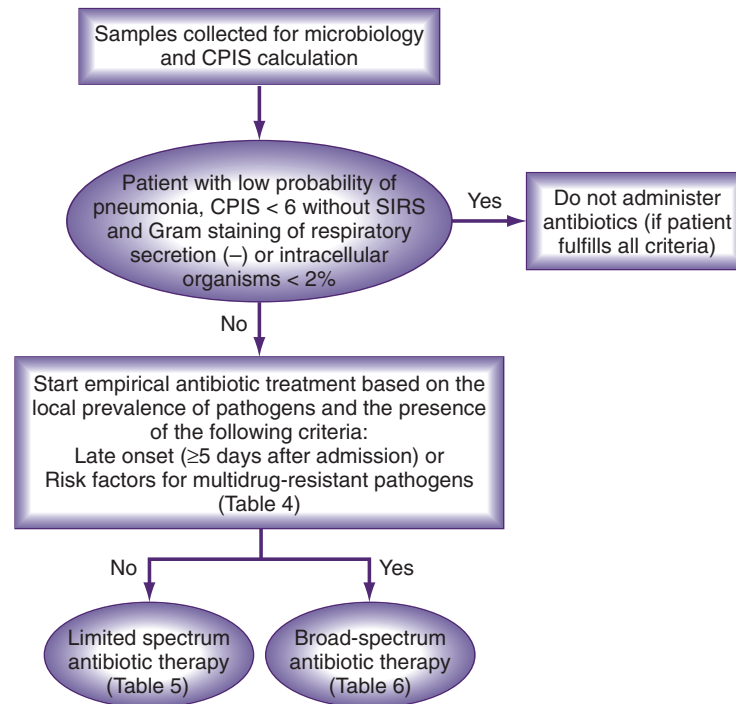

FIGURE 75-7 ■ Algorithm for the treatment of patients with suspicion of nosocomial respiratory infection. SIRS comprises at least two of the following: temperature $> 38^{\circ}\text{C}$ or $< 36^{\circ}\text{C}$; heart rate > 90 beats/min; respiratory rate > 20 breaths/min or $\text{PaCO}_2 < 32$ mm Hg; and leukocytes $> 12,000/\text{mm}^3$, $< 4000/\text{mm}^3$, or the presence of $> 10\%$ immature neutrophils. SIRS, systemic inflammatory response syndrome.

effects are dramatically reduced. Finally, nebulized antibiotics can reduce the risk of developing MDR infections.³⁰⁹

In laboratory models, nebulized amikacin reached pulmonary concentrations 30 times higher than intravenous administration. In a pivotal study by Lu et al.,³¹⁰ 20 patients with susceptible or intermediate resistant Gram-negative pathogens received nebulized ceftazidime and amikacin while 17 patients infected with susceptible strains received intravenous ceftazidime and amikacin. After 8 days of treatment, the cure rate was similar between groups. However, acquisition of treatment-associated antibiotic resistance was higher in the intravenous group. In a later study, Niederman et al.³¹¹ randomized 69 mechanically ventilated patients with Gram-negative VAP to receive aerosolized amikacin concomitantly with systemic antibiotics. They found that amikacin distributed well throughout the lung parenchyma, with high tracheal and alveolar levels, but with a serum concentration below the renal toxicity threshold.

Recently developed nebulizers increased the lung deposition of the aerosolized antibiotic dose by up to 60%. Several factors play a critical role in lung deposition of nebulized antibiotics during MV. First, the extent and severity of lung infection critically affect lung distribution of nebulized antibiotics.³¹² Second, vibrating plate nebulizers increase the efficiency of aerosol delivery to 40% to 60%.^{313,314-319} Finally, humidification^{317,320,321} and angular geometry of the ventilatory circuit should be taken into account during nebulization. In addition, ventilatory settings that ensure laminar inspiratory flow provide better distal lung deposition of aerosol particles.³²²⁻³²⁵

Antimicrobial Therapy in Special Situations

In geographic areas with a documented presence of community-acquired MRSA, severe pneumonia with radiologic images of

cavitation and presence of Gram-positive cocci in respiratory secretions, empirical treatment with linezolid or vancomycin may be appropriate. Recently, an outbreak of MRSA and linezolid-resistant *S. aureus* (LRSA) was reported in an intensive care department of a 1000-bed tertiary care university teaching hospital in Madrid, Spain, and was associated with nosocomial transmission and extensive usage of linezolid.¹⁰³ Tigecycline may be a useful alternative in this setting although clinical experience is scanty.

Infections by *L. pneumophila* serogroup 1 can be diagnosed by a *Legionella* urinary antigen test. This test should be routinely obtained if the hospital water supply is known to be colonized with *L. pneumophila* serogroup 1. A fluoroquinolone or a macrolide would be an appropriate treatment for *L. pneumophila* infection.

Modifications of Therapy and Duration of Treatment

A suggested flowchart for the follow-up of patients with nosocomial pneumonia is shown in Fig. 75-8. After 72 hours, treatment should be adjusted based on microbiological results. The initial β -lactam should be continued if the microorganism is susceptible to the empirical β -lactam originally prescribed. If not, another β -lactam should be introduced. The empirical antibiotic against MRSA should be discontinued if the presence of this pathogen is not confirmed by cultures. Discontinuation of the fluoroquinolone and especially the aminoglycoside should be considered after 3 to 5 days of treatment. The bactericidal activity of aminoglycosides and fluoroquinolones leads to a rapid reduction in the bacterial load during the first days of treatment. After this time, monotherapy may be sufficient. This approach would decrease the emergence of resistant mutants and minimize nephrotoxicity caused by aminoglycosides.

TABLE 75-4

Initial Empirical Antibiotic Treatment for Nosocomial and Ventilator-Associated Pneumonia of Late Onset or in Patients with Risk Factors for Infection by Multidrug-Resistant Pathogens and Any Degree of Severity

| PROBABLE MICROORGANISM | COMBINED ANTIBIOTIC TREATMENT |
|---|---|
| Microorganisms from Table 75-3 plus: | Antipseudomonal cephalosporin (ceftazidime or ceftipime)* |
| <i>Pseudomonas aeruginosa</i> | or |
| <i>Klebsiella pneumoniae</i> (ESBL+) [†] | Carbapenem (imipenem, meropenem)* |
| <i>Acinetobacter</i> spp. [‡] | or |
| Other nonfermenting gram-negative bacilli | β-lactam/β-lactamase inhibitor (piperacillin-tazobactam)* |
| Methicillin-resistant <i>Staphylococcus aureus</i> (MRSA) | + |
| <i>Legionella pneumophila</i> [§] | Antipseudomonal fluoroquinolone (ciprofloxacin, levofloxacin)** |
| | or |
| | Aminoglycoside** (amikacin) |
| | ± |
| | Linezolid or vancomycin*** |

*The choice of β-lactam is made as follows: patients who have not received any antipseudomonal β-lactam within the last 30 days should be administered piperacillin-tazobactam or an antipseudomonal cephalosporin. Patients who have received these drugs should be given empirical therapy with a carbapenem. Patients with infection by ESBL-producing microorganisms should be treated with carbapenem regardless of the results of the antibiogram.

**For combined empirical therapy for multidrug-resistant GNB, an antipseudomonal fluoroquinolone should be used in cases of renal failure or concomitant use of vancomycin. In other settings, combined empirical therapy is initiated with amikacin and maintained for a period of five days.

***Empirical therapy aimed against MRSA is initiated in patients with proven colonization (ψ), previous infection with this microorganism, or implementation of MV for more than six days. The antibiotic of choice is either vancomycin (except in patients allergic to this medication, with creatinine values ≥1.6 mg/dL, or in patients presenting signs of empirical treatment failure after 48 hours of antibiotic therapy) or linezolid. (Ψ) For epidemiologic surveillance, nasal and perineal cultures should be performed on admission and at 1-week intervals thereafter while remaining in the ICU.

[†]If an ESBL+ strain, such as *K. pneumoniae* or *Acinetobacter* spp. is suspected, a carbapenem is the first choice.

[‡]If *L. pneumophila* is suspected, the combination antibiotic regimen should include a macrolide (e.g., azithromycin), or a fluoroquinolone (e.g., ciprofloxacin, levofloxacin) should be used rather than an aminoglycoside.

ESBL, extended-spectrum β-lactamase; GNB, gram-negative bacilli.

The majority of infections can be effectively treated with 8 days or less of antimicrobial therapy. In a meta-analysis³²⁶ pooling data from four RCTs comparing short (7-8 days) with long (10-15 days) treatment periods, no difference in mortality was found. There was an increase in antibiotic-free days for the short-course treatment, and a trend to lower relapses in the long-course treatment was observed (OR = 1.67; 95% CI = 0.99-2.83; *P* = 0.06).

Four situations may justify prolonged treatment: (1) infection by intracellular microorganisms, such as *Legionella* spp.; (2) the presence of biofilms or prosthetic devices; (3) development of tissue necrosis, formation of abscesses, or infection within a closed cavity, such as empyema; and (4) the persistence of the original infection (such as perforation or endocarditis). If the clinical course from the pneumonia is favorable, as defined by defervescence, improvement in $\text{PaO}_2/\text{FiO}_2$, and reduction in C-reactive protein (CRP) levels within the first

TABLE 75-5

Recommended Initial Intravenous Antibiotic Dosage for Empirical Treatment of Patients with Nosocomial and Ventilator-Associated Pneumonia

| ANTIBIOTIC | DOSES | INTERVAL OF ADMINISTRATION | PERFUSION TIME |
|--|-------------|----------------------------|----------------|
| NON-ANTIPSEUDOMONAL CEPHALOSPORINS: | | | |
| Ceftriaxone | 2 g | 24 hours | 1/2-1 hour |
| Cefotaxime | 2 g | 6 hours | 1/2-1 hour |
| ANTIPSEUDOMONAL CEPHALOSPORINS: | | | |
| Ceftazidime | 2 g | 8 hours | 2-3 hours |
| Ceftipime | 1-2 g | 8 hours | 2-3 hours |
| Carbapenems: | | | |
| Imipenem | 0.5 or 1 g | 6 or 8 hours | 1 hour |
| Meropenem | 1 g | 8 hours | 2-3 hours |
| Piperacillin-tazobactam | 4 g-0.5 g | 6 hours | 2-3 hours |
| FLUOROQUINOLONES: | | | |
| Levofloxacin | 500 mg | 12 hours* | 1/2 hour |
| Ciprofloxacin | 400 mg | 8 hours | 1/2 hour |
| Amikacin | 15-20 mg/kg | 24 hours** | 1/2-1 hour |
| Vancomycin | 1 g | 8-12 hours*** | 1-3 hours |
| Linezolid | 600 mg | 12 hours | 1 hour |

*Administer this dose for three days and after continue with 500 mg/24 h.

**Adjust the dosage according to PK/PD parameters.

***Initiate this dose with 24 hours, measure trough blood levels prior to the following dosage, and adjust the levels according to values.

Dosages are based on normal renal and hepatic function.

3 to 5 days of antimicrobial therapy, treatment may be withdrawn after 7 days. If the causative microorganism is a nonfermenting gram-negative bacillus, the treatment can be extended beyond 14 days. A large prospective, multicenter, randomized trial study comparing the efficacy of 8-day and 15-day antibiotic regimens for treating VAP suggested that an 8-day regimen reduces antibiotic use and decreases the emergence of pulmonary MDR bacteria, without modification of the prognosis.³²⁷ However, this study observed that in cases of pneumonia produced by nonfermenting gram-negative bacilli, eradication of these microorganisms from bronchial secretions was lower with the shorter regimen.³²⁷ On the other hand, the 14-day treatment regimen was associated with a trend to colonization by MDR flora and a higher frequency of reinfection. Finally, in patients with clinical suspicion of ICU-acquired pneumonia who have a CPIS lower than 6 on the third day of treatment, antimicrobials may be withdrawn. In this setting, the patient likely does not have pneumonia or the pneumonia is sufficiently mild such that prolonged antibiotic treatment is not required.

Treatment Failure

At least 3 days of antibiotic treatment are necessary to achieve clinical improvement. Thus, treatment failure should be assessed between 3 and 5 days after the initiation of antibiotic therapy. The rate of treatment failure ranges between 30% and 50%, which highlights the severity and complexity of this pulmonary infection. In our previous observations,⁹² we developed a systematic definition of treatment failure comprising the following: (1) no improvement in $\text{PaO}_2/\text{FiO}_2$, or need for intubation due to pneumonia; (2) persistence of fever or hypothermia, together with purulent respiratory secretions;

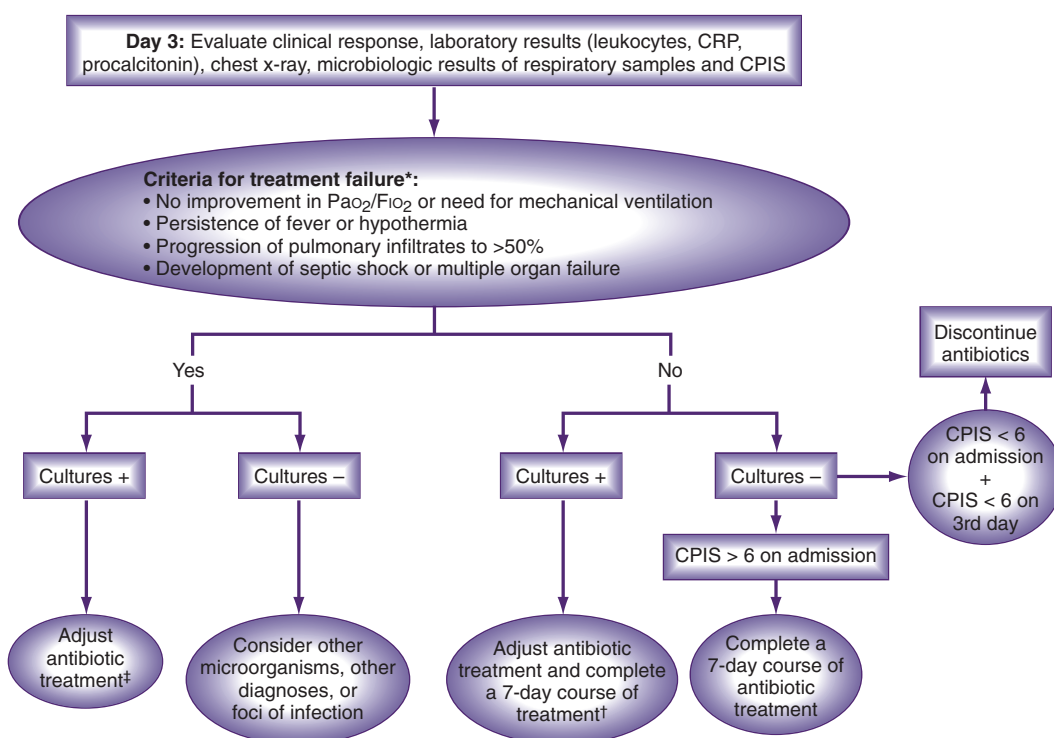

FIGURE 75-8 ■ Suggested flowchart for the follow-up of patients with nosocomial pneumonia and VAP. *Criteria of treatment failure taken from Ioannas M, Ferrer M, Cavalcanti M et al. Causes and predictors of non-response to treatment of the ICU-acquired pneumonia. Crit Care Med 2004;32:938-45. [†]In cases in which the etiologic agent is *Pseudomonas aeruginosa* or *Acinetobacter* spp., treatment should be maintained for 14 days. [‡]Patients with criteria of treatment failure and in whom MRSA is isolated should be administered linezolid. If a GNB is isolated, consultation is recommended. GNB, gram-negative bacilli; MRSA, methicillin-resistant *Staphylococcus aureus*; VAP, ventilator-associated pneumonia.

(3) increase in the pulmonary infiltrates on chest radiograph of greater than or equal to 50%; or (4) occurrence of septic shock or multiple organ dysfunction syndrome. Thus, we found that no improvement in SOFA score and $\text{PaO}_2/\text{FiO}_2$ highly predicted worse 28-day mortality. Importantly, treatment failure could be a surrogate endpoint for clinical trials to compare novel treatments. Upon evidence of treatment failure, respiratory samples should be reobtained and the initial empirical therapy rapidly readjusted. CT scan or lung ultrasound^{328,329} may help to detect cavitation, pleural effusion, and other causes for treatment failure.

Implementation of Therapeutic Guidelines

Although guideline-recommended strategies may provide significant benefits for patients, implementation is often difficult to achieve.^{330,331} Soo-Hoo et al.³³¹ developed hospital protocols to manage patients with severe hospital-acquired pneumonia based on the 1996 ATS guidelines.³³² After the guidelines were introduced into clinical settings, the authors found that adequate antibiotic therapy was administered in more than 81% of the patients with pneumonia, compared with 46% before implementation ($P < 0.01$). Moreover, a lower mortality at 14 days was found after implementation of the guidelines ($P = 0.03$). Similarly, Ibrahim and coworkers developed a protocol to provide appropriate initial antibiotic treatment for patients with VAP and encouraged a 7-day course of treatment.³³³ Thus, patients with VAP, who were treated as directed by the protocol more often received adequate antimicrobial treatment than those treated empirically (94%, in comparison to 48% before implementation; $P < 0.001$). The length of treatment was reduced by 6 days, and the second episode of VAP was less likely to occur after implementation.

KEY POINTS

1. Nosocomial pneumonia is a common complication occurring in critically ill patients and is the leading cause of nosocomial infection-related death. Ventilator-associated pneumonia develops in tracheally intubated patients.
2. Etiologic agents for ventilator-associated pneumonia differ according to the population of ICU patients, duration of hospital stay, and prior antimicrobial therapy. Nosocomial pneumonia due to multidrug-resistant pathogens is associated with the highest morbidity and mortality.
3. Preventive strategies, grouped as bundles, should be implemented in hospital settings. Several preventive strategies have shown efficacy in decreasing the incidence of pneumonia. In particular, the most effective strategies focus on reduction of cross-transmission, diminishing the likelihood of aspiration across the tracheal tube cuff, and decreasing bacterial load in the oropharynx.
4. In the presence of clinical suspicion of nosocomial pneumonia, diagnostic strategies should include an early collection of respiratory samples *before* starting or changing antibiotics.
5. The choice of empirical treatment should be based on the most likely etiologic microorganisms and the antimicrobials likely to be active against these microorganisms. Response to therapy should be reassessed after 3-5 days and antimicrobials adjusted or de-escalated to reduce the burden of the disease.

- Latest meta-analysis of randomized controlled trials that recruited adult patients in general intensive care units and studied selective digestive decontamination, selective oropharyngeal decontamination, or oropharyngeal chlorhexidine compared with standard care or placebo. Selective digestive decontamination was the only intervention that decreased mortality (OR = 0.73; 95% CI = 0.64-0.84).*
- Oostdijk EA, de Smet AM, Blok HE, et al. Ecological effects of selective decontamination on resistant gram-negative bacterial colonization. *Am J Respir Crit Care Med* 2010;181(5):doi:10.1164/rccm.200908-1210OC.
- The authors studied the effects of selective digestive decontamination and selective oropharyngeal decontamination on the development of antibiotic resistance following ICU discharge. During selective digestive decontamination, average proportions of patients with intestinal colonization with pathogens resistant to either ceftazidime, tobramycin, or ciprofloxacin were 5%, 7%, and 7%, and increased to 15%, 13%, and 13% post intervention (P = 0.05). During selective digestive decontamination and selective oropharyngeal decontamination, resistance levels in the respiratory tract were not more than 6% for all three antibiotics but increased gradually for ceftazidime during the intervention and to levels of 10% or more for all three antibiotics post intervention (P = 0.05). Thus, selective digestive decontamination and selective oropharyngeal decontamination have a marked rebound effect of ceftazidime resistance after discontinuation of intervention.*

According to the World Health Organization,¹ drowning is a serious and neglected public health threat claiming the lives of more than 372,000 people a year worldwide, or 40 people every hour of every day. More than 90% of these deaths occur in low- and middle-income countries. Whether it is small children slipping unnoticed into a pond, pool, or well; adolescents or others swimming under the influence of alcohol or drugs; passengers on vessels that capsize; or residents of coastal communities struck by floods, the toll of this global killer continues its quiet rise.

Fatal drowning is a frequent cause of death worldwide among boys 5 to 14 years of age. In the United States, drowning is the second leading cause of injury-related death among children 1 to 4 years of age, with a death rate of 3 per 100,000. In some countries, including Thailand, the death rate among 2-year-old children is more than 100 per 100,000.²

International data severely underestimate actual drowning figures, even for high-income countries.³ Epidemiologic data account for only 6% of the problem because drowning deaths are not registered in many countries. Almost all drowning victims are able to help themselves or are rescued in time by bystanders or professional rescuers. In areas where lifeguard services fully operate,² fewer than 1% of all persons rescued by lifeguards need cardiopulmonary resuscitation (CPR), and 0.3% of the rescues resulted in the death of the victim (0.34%).⁴ In one report of rescues by bystanders, almost 30% of persons rescued from drowning required CPR,⁵ demonstrating that a delay in intervention may lead to a more severe outcome than where lifeguards are on duty. Unfortunately, lifeguard or layperson rescues and first aid attendance are rarely considered in national databases, resulting in a distorted picture of drowning burden worldwide.

From 1972 to 2002 the Fire Department of Rio de Janeiro—Lifeguard Service (CBMERJ) made approximately 166,000 rescues on the beaches, and 8500 victims required attendance by the medical team in the Drowning Resuscitation Centre. With this scenario of a full lifeguard service in operation, approximately 290 rescues for each death (0.34%) were reported and one death for each 10 victims admitted for medical care in the Drowning Resuscitation Center (DRC).

The bias produced by not accounting for actual drowning figures affects not only the relative epidemiologic importance related to the problem of drowning⁶ but also gives the false impression that every drowning requires CPR and that to know how to resuscitate is the most important tool to save people from drowning.

Coastal drownings are estimated to cost more than \$273 million per year in the United States and more than \$228 million per year (in U.S. dollars) in Brazil. For every person who dies from drowning, another four receive care in the emergency department for nonfatal drowning.¹ Exposure-adjusted, person-time estimates for drowning are 200 times higher than deaths from traffic accidents.⁷

Key risk factors for drowning are male sex, age of less than 14 years, alcohol use, low income, poor education, rural residency, aquatic exposure, risky behavior, and lack of supervision. For people with epilepsy, the risk of drowning is 15 to 19 times the risk of those without.¹

Drowning deaths can be prevented in over 85% of cases by using a series of interventions.⁸ When preventive measures fail, responders need to be able to perform the necessary steps to interrupt the pathophysiologic processes associated with drowning. The first challenge is to recognize someone in the water at risk of drowning and appreciate

the need for rescue. Early self-rescue or rescue by others may stop the drowning process and prevent initial and subsequent water aspiration, respiratory distress, and medical complications. The drowning process happens quickly, but it is critical that rescuers take precautions not to become another victim by engaging in inappropriate or dangerous rescue responses.^{5,9} Removing the victim from a hostile environment has major potential for harm to the rescuer. The “drowning chain of survival”¹⁰ refers to a series of water safety interventions that when put into action by lay or professionals reduce the mortality associated with drowning.

DEFINITION

A new definition of drowning was adopted by the World Health Organization in 2002,¹¹ stating that “Drowning is the process of experiencing respiratory impairment from submersion or immersion in liquid.”

The drowning process is a continuum, beginning with respiratory impairment as the victim’s airway goes below the surface of the liquid (submersion) or when water splashes over the face (immersion). If the victim is rescued at any time, the process of drowning is interrupted, and this is called *nonfatal drowning*. If the victim dies at any time, this is a *fatal drowning*. Any submersion or immersion incident without evidence of respiratory impairment should be considered a water rescue and not a drowning. Terms such as “near-drowning,” “dry or wet drowning,” “secondary drowning,” “active and passive drowning,” and “delayed onset of respiratory distress” should not be used.¹¹ A uniform way to report data for studies on drowning and to allow comparison between different centers is to adopt the Utstein template for drowning resuscitation cases.¹²

PATHOPHYSIOLOGY

When water is aspirated into the airways, coughing occurs as an initial reflex response. In less than 2% of cases,^{13,14} laryngospasm may be present when the victim starts to inhale water. If the person is not rescued, aspiration of water continues, and hypoxemia leads to loss of consciousness and apnea. Apnea and hypoxia precede cardiac arrest. As a consequence, hypoxic cardiac arrest generally occurs after a period of bradycardia and pulseless electrical activity (PEA) and not by means of ventricular fibrillation.^{15,16} The process from immersion to cardiac arrest occurs in seconds to minutes depending on the scenario, but in unusual situations, such as when hypothermia precedes hypoxia, this process can last for up to an hour.¹⁷ In most drowning cases, cardiac function is initially relatively preserved and only ceases perfusion due to hypoxic insult after a period of apnea.^{4,9}

If the person is rescued in time during the drowning process, the clinical picture is determined by the reactivity of the airways and the amount of water that has been aspirated. Water in the alveoli causes surfactant destruction and wash-out. Salt and fresh water aspiration causes similar pathology.¹⁵ In either situation, the effect of the osmotic gradient on the alveolar-capillary membrane can disrupt its integrity, increase permeability, and exacerbate fluid, plasma, and electrolyte shifts.¹⁵ The clinical picture of damage is regional or generalized pulmonary edema (depending on the amount of water aspirated and airway reactivity) that may alter exchange of O₂ and CO₂.^{4,15,18} In animal experiments,¹⁸ aspiration of 2.2 mL of water per kilogram of body weight

leads to severe disturbance of oxygen exchange, decreasing arterial oxygen pressure (PaO₂) to approximately 60 mm Hg within 3 minutes. In humans, it seems that as little as 1 to 3 mL/kg of water aspiration produces profound alterations in pulmonary gas exchange and decreases pulmonary compliance by 10% to 40%.¹⁵ The combined effects of fluids in the lungs, loss of surfactant, and increased capillary-alveolar permeability can result in decreased lung compliance, increased right-to-left shunting in the lungs, atelectasis, and alveolitis.¹⁵

DROWNING CHAIN OF SURVIVAL

(FIG. 76-1)¹⁰

Prevent Drowning

The most effective way to reduce the number of drowning deaths is prevention. It has been estimated that 80% to 90% of all drownings are preventable.^{8,19} Drowning prevention requires multiple factors (Table 76-1).

Recognize Distress and Call for Help

The second element in the drowning chain is to recognize a person in distress in the water and know how to activate help.²¹ The Drowning Risk Assessment (DRA) identifies a person at high risk of drowning by a near-vertical body position, ineffective downward arm movements, ineffective pedaling or kicking leg actions, and little or no forward progress in the water. Professionals trained in DRA easily identify persons at risk of drowning. Sending someone to call for help upon recognizing a person in water distress is a key element that ensures early activation of professional rescue service and EMS.¹⁰

Provide Flotation to Stop the Process of Drowning¹⁰

The next priority is to interrupt the drowning process by providing flotation to the victim as an interim measure to reduce submersion risk. This buys valuable time for those on scene to initiate rescue efforts and for emergency services to arrive. Devices such as ring buoys are purposely designed to provide flotation; however, they are only available at very few locations where a drowning occurs. In most situations, improvised buoyancy aids, such as empty plastic bottles, containers, ice chests, or driftwood, should be used. It is critical that laypersons take precautions not to become another victim by engaging in inappropriate or dangerous rescue responses.^{5,9} Reaching out with, throwing, or dropping the buoyancy aid without entering the water is the preferred method of providing flotation to a drowning victim.²⁴ Also, because many victims cling to their would-be rescuer, it is better to approach a struggling victim with an intermediary object.

In-Water Resuscitation²⁵

If not interrupted, the drowning process leads first to unconsciousness and apnea, followed by cardiac arrest within minutes. During this short window of opportunity, immediate in-water ventilation may provide benefit if provided safely and effectively. For the unconscious victim, in-water resuscitation can increase the rates of discharge from hospital without sequelae by more than threefold. In-water ventilation is only possible if the rescuer is highly trained. Chest compression while the rescuer and victim are in deep water is futile, so assessment for a pulse does not serve any purpose. Victims with only respiratory arrest usually respond after a few rescue breaths. If there is no response, the

TABLE 76-1 Preventive Measures

Watch children carefully; 84% of drownings occur because of inadequate adult supervision. Begin swimming lessons from 2 years of age.
Avoid inflatable swimming aids such as “floaties” as they can give a false sense of security. Use lifejackets!
Never try to help rescue someone without being able to do it. Many people have died trying to do so.
Avoid drinking alcohol and eating lunch before swimming.
Don’t dive in shallow water, as cervical spine injury could occur.

BEACHES

Always swim in a lifeguard-supervised area.
Ask the lifeguard for safe places to swim or play.
Read and follow warning signs posted on the beach.
Do not overestimate your swimming capability—46.6% of drowning victims thought they knew how to swim.
Swim away from piers, rocks, and stakes.
Take lost children to the nearest lifeguard tower.
Over 80% of drownings occur in rip currents (the rip is usually the most falsely calm, deep place between two sand bars). If caught in a rip, swim transversally to the sand bar or let it take you away without fighting and wave for help.
If you are fishing on rocks, be careful about waves that may sweep you into the ocean.
Keep away from marine animals.

POOLS AND SIMILAR BODIES OF WATER

Over 65% of deaths occur in fresh water, even on the coast.
Fence off your pool and include a gate.
Recommended, approved fencing can decrease drowning by 50% to 70%.
Avoid toys around the pool.
Whenever infants or toddlers are in or around water, be within arm’s length, providing “touch supervision.”
Turn off motor filters when using the pool.
Always use portable phones in pool areas, so you are not called away to answer.
Don’t try to hyperventilate to increase submersion time.
Use warning sign of shallow water in the pool.
Learn CPR; over 42% of pools owners are not aware of first aid techniques. Be careful!

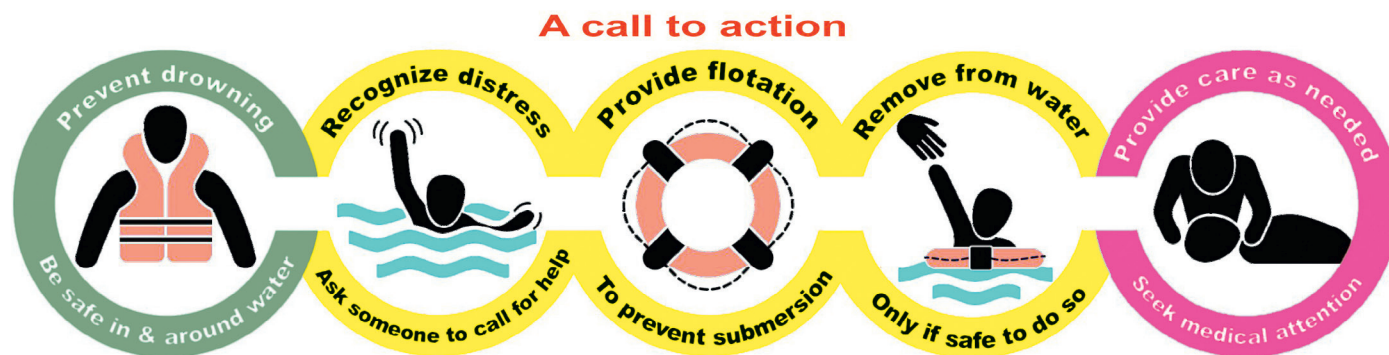

FIGURE 76-1 ■ Drowning chain of survival. (Adapted from Szpilman D, Morizot-Leite L, Vries W, et al. First aid courses for the aquatic environment. In: Bierens JJ, ed. Handbook on Drowning: prevention, rescue, and treatment. Berlin: Springer-Verlag; 2006, p. 342–7.)

victim should be assumed to be in cardiac arrest and be moved as quickly as possible to dry land where effective CPR can be initiated.

Cervical Spine Injury

Very few studies have examined how often in-water cervical spine injury (CSI) occurs.²⁶⁻²⁸ One such study retrospectively evaluated 46,060 water rescues on sand beaches and demonstrated that the incidence of CSI in this setting was very low (0.009%).²⁷ In another retrospective survey of more than 2400 drowning cases, only 11 (<0.5%) had CSI, and all had a history of obvious trauma from diving, falling from height, or a motor vehicle accident.²⁶ Considering this low incidence of CSI and the high risk to wasted time when ventilation is needed, routine cervical spine immobilization of water rescues without reference to whether a traumatic injury was sustained is not recommended.²⁹ Therefore, no attempt to immobilize the spine should be made without a strong indication and certainly not in cases where the victim appears lifeless.³⁰

Remove from Water: Rescue Only if Safe to Do So

The attempt to perform a rescue typically involves three phases: approach, contact, and stabilizing the victim. Removing the victim from water is essential to end the drowning process²⁵ and allows a setting for better assessment and care of the victim. Several strategies for removal can be used by bystander rescuers. The victim can be helped by directing them to the closest and safest place to get out of the water. If everything else fails, the lay rescuer may consider entering the water to attempt to rescue the victim by throwing, reaching, or wading to the victim.¹⁰ To mitigate risk to the bystander rescuer, the use of some type of flotation or a connecting rope is recommended, although sometimes these devices can also increase the risk.²⁴ To enter the water is a personal decision and may depend on the personal relationship with the victim (e.g., parents and children), water depth, distance to swim, and swimming skills.

The position of a drowning victim for transport out of the water is preferably as near to horizontal as possible but with the head still maintained above body level (keep horizontal if prolonged immersion or a history of immersion in cold water). The airways should be kept open at all times, if possible.³¹

Provide Care as Needed

Basic Life Support

Once on land, the victim should be placed supine with trunk and head at the same level. On beaches, this means parallel to the shore line. The standard checks for responsiveness and breathing are carried out.²⁵ If unconscious but breathing, the recovery position should be used.³¹ If the victim is not breathing, ventilation is essential.^{2,4,30} If the victim has a cardiac arrest from drowning, this is primarily due to lack of oxygen.^{4,9,30,32} For this reason, it is important that CPR follows the traditional Airway-Breathing-Circulation (ABC)^{32,33} sequence. Upper airway management is often challenging due to vomiting and the presence of pulmonary edema fluid that interferes with airway management, while at the same time pulmonary injury makes initial ventilation difficult because of decreased pulmonary compliance.^{30,35} Ventilation should be started with 5 initial breaths followed by 30 chest compressions and then continued with two breaths to 30 compressions until signs of life reappear, rescuer exhaustion occurs, or ALS becomes available. Because cardiac arrest in drowning victims is caused by asphyxia, cardiac compression-only CPR is useless.^{30,32}

The most frequent complication during drowning resuscitation is regurgitation of stomach contents, which occurs in more than 65% of victims who need rescue breathing alone, and in 86% of victims who require CPR.³⁶ The presence of vomitus in the airway can result in further aspiration injury and impairment of oxygenation.²⁵ Active efforts to expel water from the airway (abdominal thrusts or placing the victim head down) should be avoided as they only delay the initia-

tion of ventilation, increase the risk of vomiting by more than five-fold, and thereby lead to a significant increase in mortality.^{25,31}

A study has shown that less than 10% of all drowning victims are in ventricular fibrillation.³⁷ Given this, the effectiveness of an automated external defibrillator (AED) during drowning is low.

Advanced Life Support

Drowning Severity Classification. Early basic life support contributes to better outcomes from drowning and should be initiated as soon as possible.² Cardiopulmonary or isolated respiratory arrest comprises only approximately 0.5% of all rescues. In this situation, it is clear that CPR has to be started. For less serious situations, a classification system has been developed in Rio de Janeiro (Brazil) in 1972 and updated in 1997⁴ to assist lifeguards, ambulance personnel, and physicians in treatment of drowning victims. This classification was initially based on an analysis of 41,279 rescues, of which 2304 (5.5%) needed medical attention and then revalidated in 2002 by another 10-year study that included 46,080 rescues.³⁸ This classification (Fig. 76-2)² is stratified into 6 grades plus a rescue and a nonresuscitation condition encompassing support from the site of the accident to the hospital. The classification system recommends the most appropriate treatment and shows the likelihood of death based on the severity of injury. Severity is easily accessed by an on-scene rescuer, EMT, or physician using only clinical variables.⁴

To save time, medical equipment should be brought to the victim instead of the victim to the ambulance. Advanced medical treatment is given according to drowning classification.^{4,10} Recommendations for when to start and stop resuscitation are different from nondrowning-related cardiac arrest (Table 76-2).^{2,16}

For grade 6 cases (cardiopulmonary arrest⁴), resuscitation started by a layperson or lifeguard at the scene must be continued by the EMS system. The first priority should be adequate oxygenation and ventilation using bag-mask ventilation with 15 liters of oxygen until an orotracheal tube can be inserted. Meanwhile, cardiac compression should be continued. Once intubated, most victims can be oxygenated and ventilated effectively even in situations where copious pulmonary edema fluid fills the endotracheal tube. Suctioning of the orotracheal tube should be performed only when the presence of fluid makes effective ventilation impossible. Suctioning can disturb oxygenation and should be balanced against the need to ventilate and oxygenate. For cardiac monitoring, the presenting rhythm in cases of cardiac arrest following drowning is usually asystole or pulseless electrical activity (PEA). Ventricular fibrillation is rarely reported but may occur if there is a history of coronary artery disease, use of epinephrine, or in the presence of severe hypothermia.¹⁶ If ventricular fibrillation is present, defibrillation should be attempted. Peripheral venous access is the preferred route for drug administration in the prehospital setting. Endotracheal administration of drugs is not recommended for drowning.³⁴ Doses of 1 mg epinephrine IV (or 0.01 mg/kg) can be considered. After the resuscitation process is well organized, an orogastric tube can

TABLE 76-2 Drowning: When to Initiate CPR and When to Discontinue²

| QUESTION | RECOMMENDATIONS |
|----------------------|---|
| In whom to begin? | Give ventilatory support for respiratory distress/arrest to avoid cardiac arrest. Start CPR in all submersions <60 minutes who do not present with obvious physical evidence of death. |
| When to discontinue? | Basic life support should continue unless signs of life reappear, rescuers are exhausted, or advanced life support can take over. Advanced life support should be ongoing until patient has been rewarmed (if hypothermic) and asystole persists for more than 20 minutes. |

FIGURE 76-2 ■ Drowning severity classification and flow chart strategy decision based on evaluation of 87,339 rescues. ^{24,38}

be placed to reduce gastric distention and prevent further aspiration. This is particularly indicated if abdominal distention restricts ventilation. If initial resuscitation efforts are not successful, the victim should be transported to a hospital where advanced warming measures can be accomplished while resuscitation is continued during transport.

Grade 5 cases (isolated respiratory arrest⁴) are usually reversed by bystanders or lifeguards by the time advanced life support arrives at the scene. If not previously done, oxygenation and ventilation protocols as for grade 6 should be followed until spontaneous breathing is restored. If there is spontaneous ventilation, the protocol for grade 4 is followed. A grade 4 (acute pulmonary edema with hypotension⁴) patient may initially be able to maintain adequate oxygenation, although the respiratory rate is frequently elevated. Oxygenation goals are to achieve a prehospital peripheral saturation above 92% by administering oxygen by face mask at a rate of 15 L/min. Early intubation and mechanical ventilation are indicated for respiratory fatigue, even when good oxygenation is achieved using the face mask. Once intubated, most victims can be oxygenated and ventilated effectively. Patients should be sedated to tolerate intubation, and artificial mechanical ventilation providing a tidal volume of at least 5 mL/kg of body weight. FiO_2 can initially be 1.0 but should be reduced when possible. If hypotension is not corrected by oxygen, a rapid crystalloid infusion should be used.¹⁵

In grade 3 cases (acute pulmonary edema without hypotension), a therapeutic decision relates to whether there would be more benefit with initiating invasive ventilation rather than using face mask oxygenation. Only 27.6% of grade 3 drowning victims can be supported with noninvasive ventilatory support. Grade 2 patients (abnormal auscultation with rales in some pulmonary fields) usually require only oxygen by nasal cannula. In grade 1 and rescue cases, advanced medical attention and oxygen are not usually required.

As the majority of drowning victims has only mild distress or may not actually aspirate water, it is important for responders to know when to call EMS or seek medical assistance/hospital care (Table 76-3). Emergency department evaluation is recommended for all patients of grade 2 to 6 drowning.

Hospital. Decision making regarding admission to an intensive care unit (ICU) or hospital bed versus observation in an emergency

department or discharge home should include a thorough history of the incident and previous illness, physical examination, and diagnostic studies including chest radiography and ABG measurement. Electrolytes, blood urea nitrogen, creatinine, and hemoglobin also should be assessed, although perturbations in these laboratory tests are unusual. In some cases, a toxicologic screen for suspected alcohol, recreational drug use, or drug overdose might be warranted. Patients who experienced grade 3 to 6 drowning should be admitted to an ICU for close observation and therapy. Grade 2 patients can be observed in the emergency room for 6 to 24 hours, but grade 1 and rescue cases with no complaints or associated illness or trauma can be released home.

Drowning is sometimes precipitated by an injury or medical condition such as trauma, seizure, or cardiac arrhythmia. Such comorbidities should be considered⁴ after arrival in the emergency department, as they affect treatment options.

Respiratory Concerns. Grade 4 to 6 patients will usually arrive from prehospital advanced life support on mechanical ventilation with acceptable oxygenation. If not, the emergency department physician should follow standard ventilation protocols. Positive end-expiratory pressure (PEEP) should be added initially at a level of 5 cm H_2O and then increased by 2- to 3-cm H_2O increments as needed until the intrapulmonary shunt (QS:QT) is 20% or less, or $\text{PaO}_2:\text{FiO}_2$ of 250 or more is achieved. A clinical picture very similar to acute respiratory distress syndrome (ARDS) is common after significant drowning episodes (grade 3 to 6). Management is similar to that of other patients with ARDS, including efforts to minimize volutrauma and barotrauma. Lung-protective ventilation involving permissive hypocapnia probably is not suitable for drowning victims with grade 6 severity that may be associated with significant hypoxic-ischemic brain injury. In selected cases, CPAP may be provided by mask in cooperative adolescents or by nasal cannula in infants who are obligate nasal breathers, but usually this is not tolerated. If pulmonary and psychological status allows the patient to breathe without fighting, continuous positive airway pressure (CPAP) or a ventilatory pressure support mode (PSV) can be a good choice.

Pools, rivers, and beaches generally have insufficient bacteria colonization to induce pneumonia in the immediate postdrowning period.³⁹ Pneumonia is often initially misdiagnosed because of the early radiographic appearance of water in the lungs.⁴⁰ If the patient needs mechanical respiratory assistance, the incidence of ventilator-associated pneumonia increases from 34% to 52% in the third or fourth day of hospitalization as pulmonary edema is resolving.⁴⁰ Vigilance not only for pulmonary but also other infectious complications is important. Prophylactic antibiotics tend to only select out more resistant and more aggressive organisms.⁴² Daily monitoring of tracheal aspirates for Gram stain, culture, and sensitivity is advised. At the first sign of pulmonary infection, usually during the first 48 to 72 hours after drowning (as indicated by fever, sustained leukocytosis, persistent or new pulmonary infiltrates, and increased leukocyte numbers in tracheal aspirates), antibiotic therapy can be initiated using information, if available, on the predominant organism in the water where the drowning occurred. If there are reasons to suspect ventilator-associated pneumonia, antibiotics should be directed to the sensitivity of the predominant microorganisms in the ICU or by cultures if available. Fiberoptic bronchoscopy may be useful for evaluation of infection and for the rare occasions where therapeutic clearing of sand, gravel, or other solids is indicated. Corticosteroids for pulmonary injury should not be used except for bronchospasm.

The clinician must be aware of and constantly be vigilant for volutrauma and barotrauma during ventilation of drowning victims.³⁹ Spontaneous pneumothoraces are common (10%) secondary to positive-pressure ventilation and local areas of hyperinflation. Any sudden change in hemodynamic stability after mechanical ventilation is initiated should be considered to be due to pneumothorax or other barotrauma until proven otherwise.

Circulatory Issues. Cardiac dysfunction with low cardiac output is common immediately after severe drowning.¹⁵ Low cardiac output

TABLE 76-3

Who Needs Further Medical Help After Rescue from the Water

- (a) A patient who has experienced or required any of the following should be sent to a hospital:
 - Loss of consciousness, even for a brief period
 - Rescue breathing
 - Cardiopulmonary resuscitation
 - A serious condition such as heart attack, spinal injury, other injury, asthma, epilepsy, stinger, intoxication, delirium
- (b) The following persons may be considered for release from care at the scene if, after 10-15 minutes of careful observation while being warmed with blankets or other coverings as required, the patient has ALL of the following:
 - No cough
 - Normal rate of breathing
 - Normal circulation as measured by pulse in strength and rate and blood pressure (if available)
 - Normal color and skin perfusion
 - No shivering
 - Is fully conscious, awake and alert

In such cases, it is unwise for the patient to drive a vehicle, and the patient should be so advised. If any of these conditions does not apply or if the lifesaver has any doubt, then the patient should be advised to seek early medical attention.
- (c) There is always a risk of delayed lung complications. All immersion victims should therefore be warned that if they later develop cough, breathlessness, fever, or any other concerning respiratory symptoms, they should seek medical advice immediately. It is preferable that these persons not return to a home environment where they are alone for the next 24 hours.

is associated with high pulmonary capillary occlusion pressure, high central venous pressure, and high pulmonary vascular resistance and can persist for days after correction of oxygenation and perfusion abnormalities in drowning victims. This may add a cardiogenic component to drowning-associated pulmonary edema. Low blood pressure, if present, can be corrected with better oxygenation, rapid crystalloid infusion, and restoration of normal body temperature. Vasopressor infusion should be used only in refractory hypotension to improve cardiac output when replacement with crystalloid is inadequate to restore blood pressure. Urine output should be monitored by means of a Foley catheter. Echocardiography to assess cardiac function and ejection fraction can help to guide the clinician in titrating inotropic agents, vasopressors, or both if volume crystalloid replacement has failed.² In patients who are hemodynamically unstable or have severe pulmonary dysfunction, pulmonary artery catheterization may be considered to provide information concerning Starling forces in the lungs and may help in managing pulmonary edema. When pulmonary edema occurs after drowning, there is no evidence to support the use of any specific fluid therapy for salt and fresh water drowning,¹⁵ diuretics or water restriction.

Metabolic acidosis occurs in 70% of patients arriving at the hospital after a drowning episode.⁴ Acidosis should be corrected when pH is lower than 7.2 or bicarbonate is less than 12 mEq/L in spite of adequate ventilatory support. Significant depletion of bicarbonate is rarely present in the first 10 to 15 minutes of CPR, and its use is not indicated in the initial resuscitation period. In hypothermic patients, arterial blood gases do not need to be temperature corrected (the alpha-stat or pH-stat concept).⁴³

Neurologic System. The most important complication in grade 6 drowning, beyond reversible pulmonary injury, is anoxic-ischemic cerebral insult. Most late deaths and long-term sequelae of drowning are neurologic in origin.³⁹ Although the highest priority in resuscitation after drowning is restoration of spontaneous circulation, every effort in the early stages after rescue should also be directed at resuscitating the brain and preventing further neurologic damage. These steps include providing adequate oxygenation ($\text{SatO}_2\text{p} > 92\%$) and cerebral perfusion (mean arterial pressure around 100 mm Hg). Any victim who remains comatose and unresponsive after successful CPR or deteriorates neurologically should undergo careful and frequent neurologic function assessment for the development of cerebral edema and should be treated with the following measures:

- Raise the head of the bed by 30 degrees (if there is no hypotension).
- Maintain adequate mechanical ventilation.
- Ensure appropriate respiratory toilet without provoking hypoxia.
- Treat for seizure activity if present.
- Avoid overly rapid correction of metabolic alterations.
- Prevent interventions that increase intracranial pressure (ICP), including urinary retention, pain, hypotension, and hypoxia, by using sedation or muscular relaxants as necessary.
- Hyperthermia should be prevented in the acute recovery period.
- Frequently monitor blood glucose concentration, and maintain normoglycemic values.⁴⁴

Frequent monitoring of temperature is recommended in the emergency department and intensive care unit. Drowning victims with restoration of adequate spontaneous circulation who remain comatose should not be actively rewarmed to temperatures above 32°C to 34°C. If core temperature exceeds 34°C, therapeutic hypothermia (32°C–34°C) should be achieved as soon as possible and sustained for 12 to 24 hours. Although there is insufficient evidence to support a specific target PaCO_2 or oxygen saturation during and after resuscitation, hypoxemia should be avoided. Unfortunately, studies evaluating the results of cerebral resuscitation measures in drowning victims have failed to demonstrate that therapies directed at controlling intracranial hypertension and maintaining artificially high cerebral perfusion pressure (CPP) improve outcome. These studies have shown poor outcomes (i.e., death or moderate to profound neurologic sequelae) when

the intracranial pressure was 20 mm Hg or more and the CPP was 60 mm Hg or less, even when therapies were directed at controlling and improving these pressures.

Ice-Water Drowning. In some cases, hypothermia is just a reflection of prolonged submersion time and a bad prognosis. In other victims, early hypothermia is an important reason why survival without neurological damage is possible.^{30,45} Recent reports on drowning have documented good outcomes in postresuscitation patients who were kept hypothermic or treated with therapeutic hypothermia despite predicted poor outcome.^{32,46,47} Hypothermia associated with drowning can provide a protective mechanism that allows victims to survive prolonged submersion episodes.^{2,17} The rate of cerebral oxygen consumption is reduced by approximately 5% per each °C decrease in temperature within the range of 37°C to 20°C.⁴⁸

The paradox in drowning resuscitation is that the hypothermic victim needs to be warmed in order to effectively resuscitate but then may benefit from induced therapeutic hypothermia after successful resuscitation.² An important dictum that has been developed from experience with ice-water drownings and accidental hypothermia is that victims who appear dead after exposure to very cold temperatures should not be pronounced dead until they are at near-normal core temperature and remain asystolic.

Several studies have shown benefit from new therapeutic interventions for drowning victims such as extracorporeal membrane oxygenation,⁴⁶ artificial surfactant, and nitric oxide.⁴⁹

Unusual Complications. Important medical complications after drowning, other than those associated with neurologic function, are rare and are almost all restricted to patients with grade 6 severity. Rarely, some drowning victims who have normal chest radiography at initial assessment in the ED develop fulminant pulmonary edema as long as 12 h after the incident. Whether this late-onset pulmonary edema is ARDS, a neurogenic pulmonary edema secondary to hypoxia, or just an airway hyperreactive to water aspiration is unclear. Renal insufficiency or renal failure is rare in drowning victims but can occur secondary to anoxia, shock, or hemoglobinuria.

■ OUTCOME AND SCORING SYSTEMS

With advances in intensive care therapy, prognostication for drowning victims is now primarily based on neurologic outcome.⁹ Of the drowning victims with grade 1 to 5 severity, 95% return home without sequelae.⁴

In patients with grade 6 severity, prognostic variables are important when counseling family members in the early stages after the drowning incident and in deciding which patients are likely to have a good outcome with standard supportive therapy and which should be candidates for intensive cerebral resuscitation therapies.⁹

Victims who remain comatose or deteriorate neurologically should undergo intensive assessment and care.⁵⁰ Questions such as “How can we know for whom we should make the effort to resuscitate? How long should we continue to resuscitate? How should treatment differ? What should we expect as life quality after successful resuscitation?” need to be answered. Both at the rescue site and in the hospital, no single indicator for grade 6 severity appears to be an absolutely reliable predictor of outcome.² Prolonged submersion with successful resuscitation is not only possible in cold or icy water, as some anecdotal cases of warm-water drowning survival without sequelae have been described.^{4,45,51} Multiple studies^{2,4,9,12,16,17,19,25,48,50,51} have established that the outcome is almost solely determined by a single factor—duration of submersion. Basic and advanced life support enable victims to achieve their best outcome possible when the duration of cardiopulmonary arrest (submersion time included) is minimized. Most patients who show improvement and are alert (or are stuporous or obtunded but respond to stimuli 2 to 6 hours after the incident) have normal or near-normal neurological outcomes (Table 76-4).⁹

TABLE 76-4

Clinical Prognostic Score for the Immediate Period After Successful CPR Based on Glasgow Coma Score⁹

NEUROLOGIC PROGNOSTIC SCORE AFTER SUCCESSFUL CPR UPON DROWNING

| A: FIRST HOUR | B: AFTER 5 TO 8 H |
|---|---|
| Alert, 10 | Alert, 9.5 |
| Confused, 9 | Confused, 8 |
| Torpor, 7 | Torpor, 6 |
| Coma with normal brainstem functions, 5 | Coma with normal brainstem functions, 3 |
| Coma with abnormal brainstem functions, 2 | Coma with abnormal brainstem functions, 1 |
| A + B RECOVERY WITHOUT SEQUELAE | |
| Excellent, ≥ 13 | $\geq 95\%$ |
| Very good, 10-12 | 75% to 85% |
| Good, 8 | 40% to 60% |
| Regular, 5 | 10% to 30% |
| Poor, 3 | $\leq 5\%$ |

KEY POINTS

1. Drowning is a serious and neglected public health threat claiming the lives of 372,000 people per year worldwide.
2. Data account for only 6% of the cases, almost all resulting in death, giving the false impression that every drowning requires CPR and that knowing how to resuscitate is the most important tool.
3. Exposure-adjusted, person-time estimates for drowning deaths are 200 times higher than such estimates for deaths from traffic accidents.
4. The "drowning chain of survival" refers to a series of water-safety interventions that, when put into action, reduce the morbidity and mortality associated with drowning.
5. Drowning deaths can be prevented in over 85% of cases.
6. When prevention fails, the first challenge is to recognize someone in the water at risk of drowning, to appreciate the need for rescue, and to know how to help without becoming a second victim.
7. Almost all drowning victims are able to help themselves or are rescued in time. In areas where lifeguards fully operate, less than 1% of all persons rescued need cardiopulmonary resuscitation (CPR).

Pulmonary parenchymal processes in children that an intensive care clinician may encounter include common and uncommon diseases of the lower airways, alveoli, and pulmonary interstitium. Among the more challenging conditions to manage in the intensive care unit (ICU) are those that include disease or dysfunction of all three of these components, such as bronchopulmonary dysplasia and congenital diaphragmatic hernia. This chapter will discuss the pathophysiology and management principles pertinent to each disease category, with emphasis given to common examples and conditions that are unique to pediatric patients.

■ DISEASES OF THE AIRWAYS

Status Asthmaticus

Although unusual anatomic conditions of the lower airways can occur in pediatric patients (Box 77-1), status asthmaticus and bronchiolitis are the most common causes of lower airways disease encountered in pediatric ICUs. Asthma is common in the industrialized world, and the overall mortality rate attributable to asthma in the United States is estimated at 2.6 deaths per million children per year.¹ Recurrent hospitalizations, previous ICU admissions, and the need for mechanical ventilatory support have been identified as risk factors for death from asthma.² Status asthmaticus is characterized by acute, severe airway obstruction due to bronchoconstriction that is refractory to initial management with supplemental oxygen, inhaled bronchodilators, and corticosteroids. This condition begins with a precipitant that triggers contraction of hyperresponsive bronchial smooth muscles, mucous secretion, and mucosal edema, all of which lead to the obstruction of the large and small airways (Fig. 77-1). Hyperinflation from airflow limitation and premature closure of the lower airways during expiration leads to increased end-expiratory lung volume³ and increased respiratory workload, which ultimately set the stage for alveolar hypoventilation and hypoxemia. Abrupt and profound acidosis can develop when respiratory compensation for accumulated inorganic acids ceases to occur.³ On physical examination, children with status asthmaticus can appear anxious or lethargic, will often demonstrate accessory muscle use, and depending on the quality of air entry, can demonstrate either cough with profound inspiratory and/or expiratory wheezing and prolongation of audible expiration or a silent chest. An exaggerated pulsus paradoxus can often be demonstrated, a finding that reflects the profoundly negative intrapleural pressures generated by these patients during spontaneous inspiration.

Therapy

Supportive therapy for patients with status asthmaticus begins with maintaining the airways, monitoring the quality of respirations, and ensuring euvoolemia. Standard medical therapies for these patients include bronchodilators and corticosteroids. Several adjunct therapies have also been investigated as possible rescue agents in difficult cases (Table 77-1). Short-acting β -agonist agents, which mediate airway smooth muscle relaxation via local β_2 receptors,³ are the most commonly used bronchodilators for status asthmaticus. Among these agents, albuterol is the most widely used. Unlike epinephrine and isoproterenol, albuterol is relatively β_2 -selective,³ and it is most commonly administered by nebulization. It is typically given at a dose of

0.15 mg/kg (up to 2.5 mg/dose) on an intermittent basis, but only a small fraction of the nebulized dose may actually be delivered to the lung, particularly in critically ill infants and children who are intubated with small tracheal tubes.⁴⁻⁶ Some studies have shown that small doses of a nebulized β agonist given in rapid sequential fashion produce sustained improvements in forced expiratory volume more often than when larger doses are given less frequently.^{7,8} Furthermore, evidence suggests that continuous nebulization of the drug may lead to more rapid and sustained improvement.⁹

A preparation of the therapeutically active isomer of albuterol (levalbuterol) has been widely available for at least a decade. Levalbuterol appears to be effective when administered to children with stable asthma, but it is not clear that it confers any particular therapeutic advantage over its racemic counterpart in the treatment of status asthmaticus.¹⁰ One recent double-blinded, randomized controlled trial (RCT) evaluated its use in children with acute exacerbations of the disease.¹¹ The investigators randomized 81 children between the ages of 6 and 18 years who failed an initial treatment protocol consisting of three 5-mg doses of inhaled racemic albuterol, two 500-mCg doses of inhaled ipratropium bromide, and an oral or parenteral corticosteroid load to receive equipotent doses of continuous inhaled racemic albuterol (20 mg/hour) or levalbuterol (10 mg/hour). Thereafter, enrolled patients were assessed, managed, and weaned from continuous bronchodilator therapy according to a standardized inpatient treatment protocol. Mean serum (S)-albuterol concentrations in each group were similar at the time the study drug was initiated but diverged following study drug administration and remained significantly different throughout the period of continuous therapy administration (baseline S-albuterol concentration was 14.2 ng/mL in the racemic group versus 11.7 ng/mL in the levalbuterol group; S-albuterol concentrations rose to 28.6 ng/mL at 6 hours in racemic group vs. 5.5 ng/mL in the levalbuterol group; $P < 0.001$). The investigators performed both an intention-to-treat and a per-protocol analysis and could not identify any difference between study groups in the study's primary outcome, the duration of time that patients required continuous albuterol therapy (median duration of continuous therapy 18.3 hours in the racemic group vs. 16.0 hours in the levalbuterol group; $P = 0.75$ by rank-sum test). Notably, the investigators did not find any between-group difference in the mean heart rate at any time point during the continuous albuterol therapy period.

Inhaled anticholinergic agents such as ipratropium have a recognized role in the management of severe bronchospasm in children with asthma. Addition of inhaled ipratropium to inhaled β agonists has been associated with favorable changes in pulmonary function, especially in children with severe asthma.^{12,13} For patients who do not respond to inhaled bronchodilators, it is possible to administer β agonist therapy intravenously. In some countries, the intravenous preparation of albuterol is available, which allows for an alternative administration route of this β_2 -selective agent. In the United States where intravenous albuterol is not available, terbutaline, which has some β_2 selectivity, is a reasonable alternative. Although terbutaline has not been associated with clinically significant cardiac toxicity in most pediatric patients,^{3,14} many clinicians advise monitoring the ECG and serum troponin levels during its administration.

For as long as the inflammatory basis for asthma has been recognized, corticosteroids have had an important role in the management

BOX 77-1**Anatomic Causes of Lower Airway Dysfunction**

Tracheomalacia, bronchomalacia
 Vascular anomaly
 Tracheoesophageal fistula
 Idiopathic
 Bronchiectasis
 Congenital lobar emphysema
 Cystic adenomatoid malformation
 Pulmonary sequestration
 Bronchogenic cyst

TABLE 77-1**Selected Pharmacotherapies for Status Asthmaticus****NEBULIZED THERAPIES**

Albuterol (0.5%) 0.15 mg/kg/dose (0.03 cc/kg/dose) inhaled q 1-6 h prn
 Continuous inhalation 0.5 mg/kg/hour
 Ipratropium 0.25-0.5 mg inhaled q 4-6 h
 Racemic epinephrine (2.25%) 0.25-0.5 cc inhaled q 1 h prn

SUBCUTANEOUS THERAPIES

Epinephrine (1:1000) 0.01 mg/kg/dose (0.01 cc/kg/dose) SC (max 0.5 cc/dose)

INTRAVENOUS THERAPIES

Terbutaline 10 mcg/kg IV \times 1, followed by 0.4-6.0 mcg/kg/min IV infusion
 Magnesium sulfate 25-50 mg/kg IV over 20 minutes (max 2 g/dose)
 Methylprednisolone 1 mg/kg/dose IV q 6 h

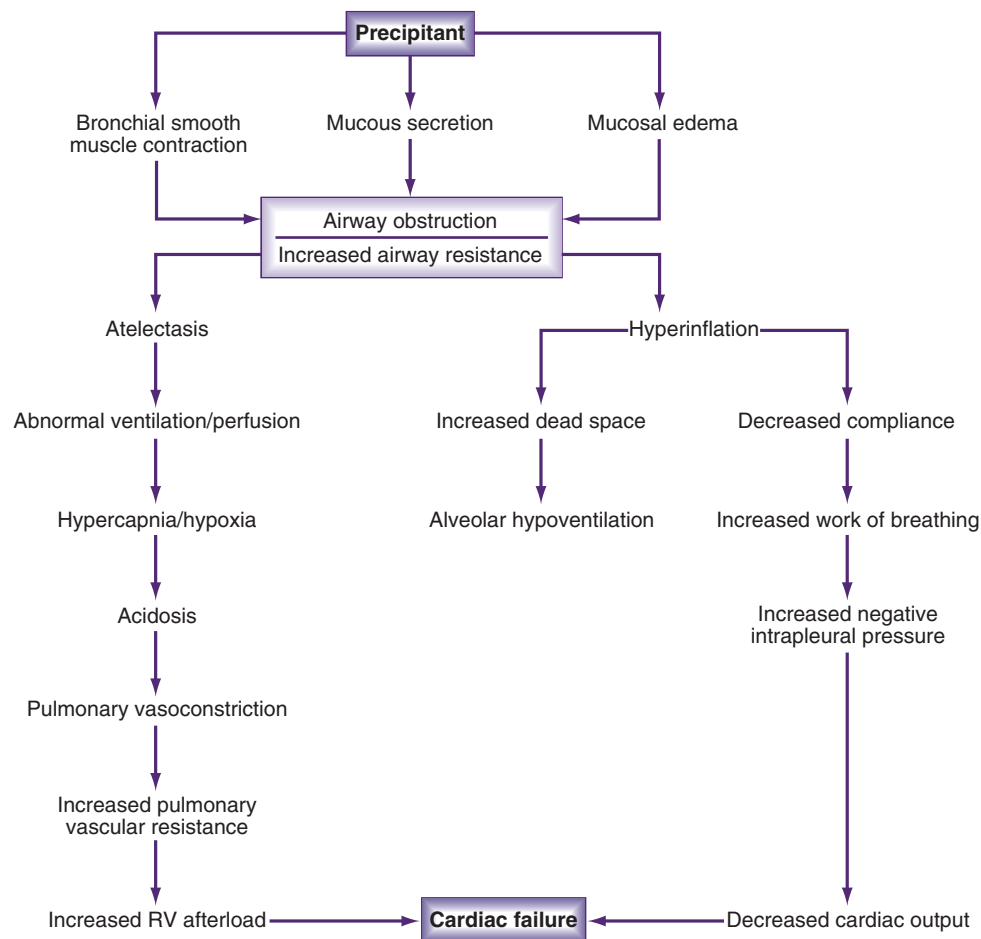

FIGURE 77-1 ■ Pathophysiology of status asthmaticus. (Modified from Helfaer M, Nichols D, Rogers M. Lower airways disease: bronchiolitis and asthma. In: Rogers M, editor. Textbook of pediatric intensive care. 3rd ed. Baltimore: Williams and Wilkins; 1996, p. 141.)

of status asthmaticus. The use of corticosteroids has been demonstrated to significantly improve airway obstruction in patients with severe acute asthma.¹⁵ The parenteral route is the method of choice for administering these agents to critically ill children, and it is important to understand that fatal anaphylaxis reactions to these drugs have been reported.^{16,17} Methylprednisolone is one of the most commonly used agents for acute severe asthma. Because of its half-life, steady-state levels can be achieved relatively quickly, and although dosing regimens

vary, it is probably most appropriate to dose the drug every 6 hours. There does not seem to be any advantage in administering massive doses of glucocorticoids to those with status asthmaticus.¹⁸ If methylprednisolone is not available, equipotent doses of another glucocorticoid may be used.

Magnesium has been investigated for use in status asthmaticus because of its potential to augment the effects of bronchodilators by causing relaxation of airway smooth muscles. A recent RCT in adults

showed that 2 g of IV magnesium sulfate improves pulmonary function when given as an adjunct to nebulized β agonists and IV corticosteroids in patients with especially low FEV1 (<20% of predicted).¹⁹ Although magnesium is occasionally added to standard therapy in pediatric patients with status asthmaticus, evidence supporting its use in this population is limited.²⁰

Enthusiasm for the use of methylxanthines (e.g., theophylline, aminophylline) in pediatric asthma has fluctuated over time. Theophylline is a preparation for enteral administration, and aminophylline is a compound for parenteral administration consisting of 80% theophylline (by weight) and 20% ethylenediamine, which is added to enhance solubility.²¹ These drugs act primarily as phosphodiesterase inhibitors, but they are believed to have a host of collateral effects that may contribute to the rationale for their use in acute asthma. These include endogenous catecholamine release,²² enhanced skeletal muscle contraction by sensitizing ryanodine receptors to intracellular calcium, and (even at low serum concentrations) attenuation of inflammatory gene expression by induction of histone deacetylase activity and suppression of NF- κ B activation.^{22,23} Importantly, methylxanthines are also nonselective adenosine receptor antagonists.^{22,24} Their interaction with the A_{2B} receptor, which is located on the bronchial tree and is known to mediate bronchospasm, may be of particular importance in producing their bronchodilatory effects. A recent RCT investigated the effects of aminophylline in 163 children with status asthmaticus. Aminophylline was administered to these children as an adjunct to nebulized β agonists, nebulized anticholinergics, and parenteral corticosteroids.²⁵ The results of this trial suggested that aminophylline improved pulmonary function and that it may have averted intubation in a portion of patients who received it.²⁵ Although aminophylline may have a role in the treatment of those with severe status asthmaticus who do not respond to standard therapies, the potential for its widespread use is limited by its narrow therapeutic index.³

Bronchiolitis

Bronchiolitis is a clinical term implying an invasion of the large and small airway respiratory epithelium by inflammatory cells in the setting of acute respiratory illness. The most common cause of bronchiolitis is respiratory syncytial virus (RSV), which is responsible for 45% to 80% of cases.²⁶ Parainfluenza viruses, human metapneumovirus (hMPV), enteroviruses, adenovirus, influenza viruses, and *Mycoplasma pneumoniae* can produce the syndrome as well. Hospitalization rates vary seasonally and regionally in infants and children with bronchiolitis arising from any of these causes. Recent temporal trends in the rates of hospitalizations for all-cause bronchiolitis indicate that between 2000 and 2009, there was a 17% decrease in the incidence of bronchiolitis-related hospitalizations among all children less than 2 years of age in the United States, while the proportion of hospitalized children with a history of prematurity and one or more chronic medical conditions increased 34% during the same time period (5.9% in 2000 vs. 7.9 in 2009; $P_{\text{trend}} < 0.001$).²⁷ Adjusting for inflation, total hospital charges increased from US\$1.34 billion in 2000 to US\$1.73 billion in 2009 ($P_{\text{trend}} < 0.001$), a finding illustrating the substantial contribution of bronchiolitis-related hospitalizations to overall health-care costs.²⁷

To put the epidemiology, pathophysiology, and clinical sequelae of bronchiolitis into a more meaningful context, it is useful to understand the taxonomy describing the genetic relationships among the important causative pathogens (Table 77-2).

Pneumovirinae: Human Metapneumovirus and Respiratory Syncytial Virus Bronchiolitis

In accordance with their genetic homology, RSV and hMPV share most of their encoded proteins²⁸ and establish infection in young children worldwide with astonishing reliability. RSV dependably causes yearly epidemics during the winter and spring months in most geographic regions. Infection with RSV is nearly universal among

TABLE 77-2

Taxonomy of Viruses That Are Important Causal Pathogens of Acute Bronchiolitis

| FAMILY | SUBFAMILY | VIRUS |
|-----------------|------------------------|---|
| Paramyxoviridae | <i>Pneumovirinae</i> | RSV ¹ hMPV ² |
| | <i>Paramyxovirinae</i> | Parainfluenza virus |
| Picornaviridae | | Enterovirus species A, B, C, D |
| | | Rhinovirus ³ species A, B, C |

¹Respiratory syncytial virus; ²Human metapneumovirus; ³Rhinovirus species A, B, and C are now classified within the genus *Enterovirus*.⁴⁵

infants and children by 2 years of age, and after 5 years of age, almost all children show serologic evidence of prior infection with hMPV.²⁹ Each of these viruses has developed a distinct repertoire of techniques to evade the host immune response. hMPV, for example, subverts the innate immune response by inhibiting Toll-Like Receptor (TLR) 4 and TLR 7–dependent activation of the cascade of cellular signaling events in airway epithelial cells that culminate in the expression of interferon- α and - β .²⁸

The various strategies RSV has evolved to sustain its presence in infected hosts serve as key mediators of important causal pathways connecting acute and/or recurrent infections with its enduring pathophysiologic consequences. In vitro experiments using immunofluorescence and flow cytometry on human nasal, tracheal, and bronchial epithelial cell lines confirm that RSV infection triggers distal airway epithelial cells to elaborate nerve growth factor (NGF) and its high-affinity receptor trkA, which is responsible for promoting the expression of antiapoptotic bcl-2 regulatory proteins.³⁰ Concurrently, infection of the distal airways triggers the downregulation of NGF's low-affinity receptor p75^{NTR}, which is normally responsible for initiating a molecular signaling cascade culminating in a proapoptotic paradigm mediated by NF- κ B, stress-activated c-Jun N-terminal protein kinases (JNK), and ceramide activation.^{30,31} By subverting these redundant components of the immune response, RSV is able to maintain a prolonged presence in distal airway epithelial cells, allowing them to accommodate ongoing viral replication and local viral propagation (Fig. 77-2).^{31,32} The approaches RSV takes to maintain an extended presence in an infected host are expressed in extrapulmonary settings as well. In 2011, Rezaee and colleagues were the first to demonstrate that RSV infects human bone marrow cells.³³ They established that RSV can efficiently infect and take refuge in human bone marrow cells, allowing the virus to modulate the immune response to acute infection and perhaps serve as a reservoir of latent disease.^{32,33}

RSV transmission can occur either by direct contact with contagious secretions or by exposure to aerosolized particles from the respiratory mucosa.³⁴ The incubation period varies from 2 to 8 days³⁴; symptoms tend to escalate over 3 to 5 days, and convalescence can be prolonged for up to several weeks in the most vulnerable small infants. A histologic examination shows that reappearance of ciliated respiratory epithelium commonly takes more than 2 weeks.³⁴ Viral shedding from the respiratory tract typically occurs over 3 to 8 days but may continue for up to 4 to 6 weeks in small infants. Symptoms typically begin with signs of upper respiratory illness including fever, coryza, and possibly, otitis media. Small infants commonly present with lethargy and central apnea³⁵ early in the course of illness. Cough and tachypnea soon develop as the illness progresses to the lower airways, usually 1 to 3 days following incubation.³⁴ Radiographic findings commonly include hyperinflation, peribronchial thickening, subsegmental consolidation, and multiple areas of atelectasis or infiltration, most frequently involving the right middle and right upper lobes. A large prospective study of RSV-infected hospitalized children found that

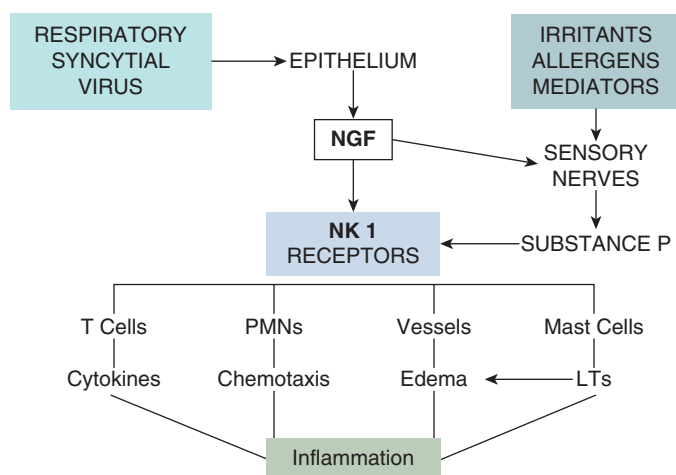

FIGURE 77-3 ■ Neuroinflammatory mechanisms incited by RSV infection, which can be reactivated by environmental exposures to produce recurrent wheezing. RSV preferentially invades and replicates in distal airway epithelial cells, increasing NGF production and upregulating the substance P receptor neurokinin (NK)-1 on a variety of immune cells. This process results in activation of neuroinflammatory pathways and longer term neural remodeling of infected airways. In small animals uninfected with RSV, NGF expression declines with age, whereas RSV infection greatly increases NGF expression across the age spectrum. Exposure to anti-NGF antibody inhibits the upregulation of NK-1 receptors.²²² LTs, leukotrienes; NGF, nerve growth factor. (From Piedimonte G. Pathophysiological mechanisms for the respiratory syncytial virus-reactive airway disease link. *Respir Res* 2002;3: S21–S25.)

Picornaviridae: Enteroviral Bronchiolitis and the Resurgence of Enterovirus D68

Within the genus *Enterovirus*, both *Rhinovirus* and *Enterovirus* species are among the important causal pathogens of bronchiolitis. Like RSV, human rhinovirus infection enhances expression of NGF and its trkA receptor in airway epithelial cells, an event with the dual consequence of creating a hospitable setting for ongoing viral replication and potentiating postinfectious airway hyperreactivity by setting the stage for neurokinin-1-mediated neural remodeling in distal airways.³² In rhinoviral infections, elaboration of NGF and upregulation of trkA also enhance viral attachment by increasing expression of intercellular adhesion molecule-1 (ICAM-1), the principal receptor by which rhinoviruses gains access to susceptible airway epithelial cells.⁴³

In 2014, the role of enteroviruses in the pathogenesis of bronchiolitis reestablished itself in the collective consciousness of pediatric clinicians with the widespread outbreak of severe lower respiratory illness caused by *Enterovirus* D68 (EV-D68). This virus was first recovered from the oropharynx of four children between 10 months and 3 years of age who were hospitalized in California with acute lower respiratory tract infection and wheezing during the autumn of 1962. Schieble and colleagues were subsequently able to isolate the virus in cell culture.⁴⁴ The virus was classified within the family Picornaviridae as a novel enteroviral serotype that became known as the “Fermon” strain of EV-D68.⁴⁴ Like the rhinoviruses, and unlike other enteroviruses, EV-D68 preferentially infects the respiratory tract rather than the GI tract and is transmitted principally through contact with respiratory secretions. During its 3- to 6-day incubation period, EV-D68 establishes its presence in the host respiratory epithelial cells through a sequence of events beginning with an attachment process mediated by the interaction between viral capsid components encoded by amino acid sequences VP1, 2, and 3 and sialic acid on the epithelial cell surface.⁴⁵

FIGURE 77-4 ■ Representative brain and spinal cord MR images in setting of EV-D68 infection with flaccid paralysis and cranial nerve dysfunction. Taken in the acute phase of illness, axial images **A**, **B**, and **C** show T2 hyperintensity in the right dorsal pons (white arrow, Panel **A**) and central hyperintensity in the central gray matter (white arrows, Panels **B** and **C**). Sagittal cord images show a progression from an extensive, ill-defined T2 hyperintensity in the acute phase of illness (black arrows, Panel **D**) to a signal hyperintensity that coalesces around the anterior horn cells 38 days into illness (black arrows, Panel **E**). (Modified from Maloney JA, Mirsky DM, Messacar K, et al. MRI findings in children with acute flaccid paralysis and cranial nerve dysfunction occurring during the 2014 enterovirus D68 outbreak. *Am J Neuroradiol* 2015;36:245–250; Fig. 4.)

Confirmed reports of respiratory illness attributed to EV-D68 were limited to 26 cases between 1970 and 2005; 75% of these occurred in children.⁴⁵ Another 95 confirmed cases were reported from the Philippines, Japan, the Netherlands, and the United States between 2008 and 2010. The widespread outbreak in the United States during 2014 is the largest to date, having involved over 1150 patients throughout the country. Traditionally, the symptom complex that was observed along with EV-D68 related respiratory disease included cough, dyspnea, wheezing, and increased work of breathing, with peripheral bandemia often noted on complete blood counts.⁴⁵ By historic standards, the 2014 cases presented with especially morbid disease, and 12 of the affected children died. Notably, the 2014 United States outbreak featured a cohort of 12 children in Colorado ranging from 1 to 16 years of age (median age 11.5 years) who developed acute onset of flaccid paralysis, cranial nerve dysfunction, and concordant spinal cord and brainstem abnormalities on magnetic resonance imaging (MRI), a median of 7 days after a prodromal febrile illness (Fig. 77-4).⁴⁶ The clinical findings in these cases resonated with case reports published between 2005 and 2014 that first suggested a possible association between EV-D68 infection and the development of acute motor neuropathy and/or anterior myelitis.^{47–49} Nasopharyngeal samples were positive for *Rhinovirus* or *Enterovirus* in 8 of the Colorado children; 5 of these 8 samples later revealed the presence of EV-D68. CSF

pleocytosis was present in all 10 children from whom it was obtained (median 55 cells/ μ L), yet *Enterovirus* could not be isolated from any of the CSF samples. Nonetheless, the pattern of neurologic involvement in these children and the absence of evidence for other candidate infections or autoimmune diseases implicate an *Enterovirus* (namely, EV-D68) as a possible cause. Follow-up of the Colorado cohort is still ongoing. While many have shown partial resolution of their neurologic findings, all 10 children who developed limb weakness were showing residual deficits as of December 1, 2014.⁴⁶

It is perhaps owing to more reliable diagnostic techniques that the prevalence of EV-D68–related respiratory illness seems to have increased over the past 40 years. Highly sensitive multiplex polymerase chain reaction (PCR) assays have certainly facilitated rapid diagnosis since they became available over the past decade, but because they target genetic sequences common to both *Enterovirus* and *Rhinovirus* species, they are unable to distinguish between the two.⁴⁵ A more specific diagnostic technique targeting the VP1 gene sequence has been available since 1999, and facilitated identification of EV-D68 as the causal pathogen of the U.S. outbreak that unfolded in 2014, allowing for crucially important early surveillance efforts.^{45,50}

Therapy

Many years of clinical experience with empiric use of symptomatic medical therapies have failed to determine a clear role for any of these agents in the management of bronchiolitis. Widespread use of bronchodilators and corticosteroids for the management of bronchiolitis is common despite the absence of evidence for meaningful improvement in relevant clinical outcomes for hospitalized and/or critically ill children.^{53–58} A few small studies have associated some short-term physiologic benefit with the use of corticosteroids and immune globulin in critically ill infants and children with bronchiolitis, but the efficacy of these therapies in altering outcomes in this population remains unproven.⁵³ Following from the observation that critically ill children with severe bronchiolitis demonstrate surfactant deficiency and dysfunction, a great deal of interest has surrounded the use of exogenous surfactant to modify the course of bronchiolitis in intubated patients. A number of small, underpowered trials have been conducted on this topic,^{59–61} but the available data do not provide a reliable estimate of surfactant's effects in this setting.⁶² Interpretation of this literature is complicated by the fact that the choice of surfactant preparation, the dosing regimen, and the mechanical ventilation strategy vary across studies.⁶² One recent multicenter RCT evaluated the impact of the semisynthetic surfactant Lucinactant (Discovery Laboratories, Warrington, PA) on duration of mechanical ventilation among children 2 years or less in age, with acute hypoxemic respiratory failure meeting criteria for acute lung injury (ALI) or the acute respiratory distress syndrome (ARDS), a portion of whom had bronchiolitis.⁶³ This was a phase 2 trial designed to examine the safety, tolerability, and potential efficacy of Lucinactant for shortening the duration of mechanical ventilation through 14 days following study entry. The study randomized 165 infants from PICUs in the United States and Chile to receive intratracheal Lucinactant (175 mg/kg) or an equivalent volume of air placebo; an additional dose of Lucinactant could be administered to patients in the intervention group if they met predetermined redosing criteria. Unfortunately, the study protocol did not mandate a standardized approach to ventilator management or extubation readiness testing. It was not able to detect a significant decrease in the duration of mechanical ventilation that could be attributed to Lucinactant (least square mean: 4.0 days for Lucinactant group vs. 4.5 days in placebo group; $P = 0.25$). Fifty serious adverse events occurred in 34 patients in this study (20 Lucinactant patients vs. 14 placebo patients); two were attributed to study drug administration.

The latest guidelines issued by the American Academy of Pediatrics emphasize supportive care for hospitalized infants and children with viral bronchiolitis, and recommend against the routine use of aerosolized bronchodilators and systemic corticosteroids in this population.⁴² Supportive care of the patient with bronchiolitis consists of an ongoing assessment of airway patency, the adequacy of respirations, and

maintenance of adequate circulating volume. Supplemental oxygen is often required to reverse hypoxemia, and the clinician should be attentive to changes in mental status that could signal impending respiratory failure. Because future prospects for providing lasting immunity to RSV remain doubtful,³⁴ there is an ongoing need for large, multicenter studies to identify therapies that may benefit critically ill children with this disease.

Mechanical Ventilation

The need for mechanical ventilation in patients with lower airways disease commonly arises from failure of ventilation and the resulting hypercapnia. Hypoxemia and recurrent apnea, which are common in young infants with bronchiolitis, also frequently precipitate the institution of ventilatory support. Assuming adequate airway protection, oxygenation, and respiratory drive, it is probably best to avoid intubation in patients with lower airways disease unless the overall clinical status warrants the risk of augmenting airway hyperreactivity through airway instrumentation.⁶⁴ There are several adjunct therapies that may obviate the need for intubation when added to aggressively applied conventional therapies. An inspired mixture of helium and oxygen (heliox) has been used to alleviate airflow limitation in pediatric patients. Due to its low density and reduced Reynolds number, helium is able to convert turbulent gas flow to laminar flow in the airways, and its clinical effect is generally immediate. Because it is an inert gas, it can potentially reduce airways resistance without toxicity. When given as 60% to 80% of the total inspired gas mixture, helium can produce more efficient delivery of oxygen and nebulized drugs.⁶⁵

The use of heliox in patients with lower airways disease has generally produced inconsistent results. A small RCT in spontaneously breathing children with status asthmaticus demonstrated that administration of heliox improves respiratory mechanics by lowering the pulsus paradoxus, increasing peak flow, and decreasing the dyspnea index, which may decrease the need for mechanical ventilation.⁶⁶ In another small series, a 60:40 heliox mixture administered to 7 intubated patients resulted in a 15% to 50% reduction in peak inspiratory pressure and a 30% to 60% reduction in P_{aCO_2} .⁶⁷ A recent literature review on the use of heliox in patients of all ages with acute asthma concluded that it may be useful in the short-term management of these patients, but any advantage attributed to its use seems to have diminished over time.⁶⁸ There is little evidence available on the use of heliox in critically ill patients with bronchiolitis. This issue was prospectively investigated in a nonrandomized study of 38 nonintubated infants with RSV bronchiolitis admitted to an ICU.⁶⁹ Favorable changes in respiratory status through the first 4 hours of heliox administration and a significant decrease in length of ICU stay were seen among infants who received heliox therapy.⁶⁹ In a small randomized, crossover study of RSV-positive, nonintubated patients, clinical indicators of respiratory status improved during heliox administration, particularly among children with more severe disease.⁷⁰ However, many of these patients required another form of respiratory support, and the study was not designed to evaluate longer term outcomes such as length of ICU stay.⁷⁰

The application of noninvasive forms of mechanical support such as CPAP or bilevel positive pressure using either a nasal interface or full face mask has potential advantages in patients with adequate respiratory drive. Careful titration of applied CPAP (or PEEP) may prevent premature airways closure during expiration and decrease gas trapping (see later discussion). Patients who develop high levels of intrinsic PEEP due to hyperinflation manifest increased work of breathing and ultimately, respiratory muscle fatigue that may precipitate dramatic and rapid clinical deterioration. Noninvasive respiratory support may allow unloading of the muscles of respiration without adding to airway reactivity and has been used with success in managing asthma as well as bronchiolitis.^{71,72}

In patients with respiratory failure where noninvasive mechanical support is not feasible, intubation and mechanical ventilation are warranted. As tracheal intubation is performed in patients with airways

disease, the clinician should be watchful for complications arising from the transition to positive pressure ventilation. In spontaneously breathing children with severe airway obstruction, profoundly negative intrathoracic pressures develop in order to generate lung inflation. These conditions produce maximal venous return as right atrial pressure remains subatmospheric.⁷⁴ The transition to positive pressure ventilation in this setting increases juxtacardiac pressures and right ventricular afterload, resulting in decreased venous return, decreased left ventricular compliance, and decreased left ventricular end diastolic volume,⁷⁴ with risk of hypotension and cardiac arrest.³

In intubated patients with status asthmaticus or bronchiolitis, low elastic recoil and increased airway resistance due to bronchoconstriction, airway edema, and mucous plugging contribute to regional gas trapping and dynamic hyperinflation (Fig. 77-5, A). Gas trapping can also be exacerbated by the patient's forced expiratory efforts, during which increased abdominal pressure is transmitted to the pleural space, potentiating premature airways closure and the development of excess or intrinsic PEEP ("auto-PEEP"). The magnitude of the auto-PEEP reflects the degree of dynamic hyperinflation in patients with severe asthma.⁷⁵ Dynamic hyperinflation and auto-PEEP have an adaptive purpose in increasing the elastic recoil pressure of the lung to a level that would eventually allow complete evacuation of inhaled volume.⁷⁵ However, this increase in lung volume takes place at the

expense of an unfavorable change in pulmonary compliance. Other potential consequences of dynamic hyperinflation and auto-PEEP include air leak, hemodynamic compromise from sustained elevations in pulmonary vascular resistance, and increased inspiratory workload from the patient's attempts to drop the ventilator circuit pressure below the total PEEP level (applied or set PEEP plus auto-PEEP) in order to trigger a breath (Fig. 77-5, B). The development of gas trapping and auto-PEEP can be inferred if the flow versus time waveform on the ventilator console shows initiation of inspiratory flow before the expiratory flow from the preceding breath reaches zero. Alternatively, the ventilator can quantify auto-PEEP by allowing the alveolar pressure to equilibrate with pressure at the airway openings during an end-expiratory hold maneuver. The accuracy and reliability of each of these techniques rest on the premise that all lung units communicate with the airway openings, which may not be true if bronchial obstruction is severe.⁷⁶

Excessive gas trapping and auto-PEEP are managed through adherence to the basic principles of mechanical ventilatory support of patients with lower airways disease: (1) limitation of tidal volume, plateau pressure, and respiratory rate; (2) reducing inspiratory time; and (3) judiciously titrating applied PEEP. In spontaneously breathing mechanically ventilated patients, increases in applied PEEP can reduce auto-PEEP by reducing the tendency to premature airway closure during exhalation and restoring a pressure gradient between the alveoli and airway opening that favors a return toward normal end-expiratory lung volume. Reduction of auto-PEEP through this kind of maneuver can trigger ventilator breaths and decrease the inspiratory workload. It turns out that this concept can be difficult to optimize in practice. If increases in applied PEEP fail to improve respiratory mechanics or worsen gas trapping, the clinician may consider a trial of neuromuscular blockade in an effort to facilitate enforcement of permissive hypercapnia and further reductions in minute ventilation.

In summary, initial ventilator settings in patients with lower airways disease should be guided by observation, auscultation, careful ventilator waveform analysis, and attention to inspiratory plateau pressure. Ultimately, the choice of ventilator mode is not as important as a thorough understanding of how any mode might be strategically manipulated to alleviate the pathophysiology of gas trapping and auto-PEEP. It is generally preferable to allow patients to breathe in a spontaneous ventilator mode, using a strategy of permissive hypercapnia. In spontaneously breathing mechanically ventilated patients, applied PEEP can be titrated cautiously upward as needed to improve respiratory mechanics, to a level not exceeding 80% of auto-PEEP, or until the plateau pressure begins to exceed a tolerable limit, which is usually around 30 cm H₂O.^{76,77} If controlled ventilation is necessary, it is preferable to apply the lowest minute ventilation that provides adequate gas exchange.⁷⁸ The use of neuromuscular blocking agents should be limited to the shortest feasible course, because of their potentially detrimental effect on the relationship between ventilation and perfusion, and because of the risk of myopathy when these agents are administered together with corticosteroids.⁷⁹ High-frequency oscillatory ventilation (HFOV, see below) has been used to rescue a limited number of pediatric patients with asthma and bronchiolitis who demonstrate respiratory failure refractory to management with conventional ventilation.⁸⁰ One recent report recommends the use of high distending pressures to decrease airway resistance, low frequencies, longer expiratory times, and muscle relaxation in order to minimize gas trapping.⁸¹

Sedation is an important component of managing intubated patients with lower airways disease. Besides alleviating distress and promoting synchrony with the ventilator, sedative agents can be helpful adjuncts in limiting carbon dioxide production and reducing mechanical ventilatory requirements.⁷⁶ Ketamine, a dissociative anesthetic with sympathomimetic and bronchodilatory properties, is often used for sedation in intubated asthmatic children.⁸² Because of its favorable effects on airways reactivity, the inhalational anesthetic isoflurane (Forane®; Baxter Healthcare, Deerfield, IL) may be a useful adjunct to the management of severe status asthmaticus in intubated children

FIGURE 77-5 ■ A, Dynamic hyperinflation. Expiratory flow limitation in the asthmatic lung (upper tracing) causes incomplete evacuation of lung volume at end exhalation. Repetitive cycles of gas trapping lead to excess pressure accumulation at end exhalation ("auto-PEEP"), with a progressive shift toward ventilation on the less compliant (upper and outer) portion of the pressure-volume curve. (See also Fig. 77-6.) **B, Effect of auto-PEEP on inspiratory threshold load.** Ventilator circuit pressure, alveolar pressure, and trigger sensitivity setting are indicated. The difference between peak inspiratory circuit pressure and peak inspiratory alveolar pressure reflects the increased airway resistance. The difference between the end-expiratory circuit pressure and the end-expiratory alveolar pressure reflects the expiratory flow limitation and auto-PEEP. The pressure drop required to generate inspiratory flow ("trigger threshold") is the difference between the end-expiratory pressure and the sensitivity setting. In the presence of auto-PEEP, the patient must generate a larger inspiratory pressure drop in order to generate inspiratory flow. (A, From Stather DR, Stewart TE. Clinical review: Mechanical ventilation in severe asthma. *Crit Care* 2005;9:581-587.)

who are difficult to sedate or are unresponsive to other therapies. The mechanism underlying its bronchodilatory properties is not well understood.⁸³ Although isoflurane (Forane®; Baxter Healthcare, Deerfield, IL) has a better safety profile than halothane when used for this purpose, periodic monitoring of renal function may be advisable in children who require prolonged therapy with this agent.⁸³

■ DISEASES OF THE ALVEOLI

Viral Pneumonia

Defined as acute respiratory symptoms accompanied by parenchymal infiltrates on chest x-ray, pneumonia is a common syndrome in children and is most commonly caused by viral or bacterial pathogens.⁸⁴ Important viral pathogens responsible for pneumonia in infants and children include RSV, influenza, parainfluenza, and adenovirus. As we have seen, each of these agents is also capable of producing the clinical syndrome of bronchiolitis in infants and children. The precise infectious etiology for pediatric viral pneumonias may be suggested by the physical examination, the age of the patient, and seasonal incidence patterns. Confirmatory testing through microbiologic analysis is generally sought to facilitate therapeutic decision making and cohorting of similarly affected patients. RSV is the most common viral cause of lower respiratory tract infection in infants⁸⁵ and primarily affects the small airways. Parainfluenza viruses are also responsible for causing pneumonia in children and seasonal epidemics that commonly occur in autumn.⁸⁵ Primary infections tend to occur in young children 2 to 6 years of age, and recurrent infection is generally less severe, except perhaps in immunocompromised hosts.⁸⁵ Finally, adenoviruses have been reported to cause up to 20% of pneumonias in children less than 5 years of age, and the mortality rate attributable to the disease has been reported to be as high as 20%.⁸⁶ In neonates, adenovirus can produce an especially severe syndrome of disseminated disease and sepsis, which can present in the first 10 days of life.⁸⁶ The incubation period is 2 to 14 days,⁸⁵ and the virus can produce a profound and destructive lower respiratory process. Necrotizing bronchitis, purulent exudative alveolitis, and hyaline membrane formation have been identified on autopsy.⁸⁶ Survivors of severe adenoviral infections often demonstrate chronic sequelae such as recurrent wheezing and *bronchiolitis obliterans*, a syndrome of irreversible fibrosis characterized by a heterogeneous pattern of airway narrowing in some lung units and complete eradication of the airway lumen in others.^{86,87}

Influenza is a particularly important cause of pediatric pneumonia. Infection rates in healthy children are estimated at 10% to 40% each year, and approximately 1% of these children require hospitalization.⁸⁵ The course of up to 25% of infected children is complicated by lower respiratory tract disease.⁸⁵ Neonates and children up to 5 years of age, especially those who are immunocompromised, those with underlying lung disease, congenital heart disease, and other chronic conditions, seem to be at special risk for influenza pneumonia.⁸⁵ Neonates are at risk for especially severe influenza syndromes, which may also include apnea and sepsis.⁸⁵

The clinical course of influenza observed during the 2009 H1N1 pandemic diverged from what had typified prior seasonal patterns. It often featured rapidly progressive hypoxia and respiratory failure^{88,89} and was more frequently associated with concurrent shock in children and increased mortality.⁹⁰ Several case series of critically ill children and adults with the 2009 H1N1 infection included a cohort of patients who manifested particularly fulminant ARDS.^{88,89,91-93} Multicenter observational studies conducted across Canada,⁹² the United Kingdom,⁹³ and the United States⁹⁴ reported an ICU mortality rate of 7% to 9% for children with H1N1-associated respiratory failure. The cohort in the United States showed a propensity for early pulmonary co-infection with methicillin-resistant *Staphylococcus aureus* (MRSA), a finding that was strongly associated with mortality in previously healthy children who became critically ill with H1N1 disease (relative risk of death = 8; 95% CI, 3.1-20.6; $P < 0.0001$).⁹⁴

Therapy

Antiviral therapy for A and B strains of influenza are now available and can be considered for patients of appropriate age who are at high risk of complicated or severe disease.⁸⁵ When administered within 48 hours of disease onset, amantadine, which is approved for use in children less than a year old, may decrease the severity of influenza A disease, but data in young patients are limited.⁸⁵ Oseltamivir, an orally administered neuraminidase inhibitor active against both A and B strains of influenza, has been shown to decrease symptom duration when administered early in the disease process. When originally licensed for pediatric administration, oseltamivir was not approved for use in infants less than a year old.⁹⁵ However, increased experience with oseltamivir in smaller infants during the 2009 H1N1 influenza pandemic has produced some consensus on appropriate dosing guidelines in this age group.⁹⁶ The Centers for Disease Control and the American Academy of Pediatrics now recommend oseltamivir for treatment of influenza in infants and children of *any age* who are hospitalized, have a severe, progressive, or complicated trajectory of illness, or are at higher risk for influenza complications.⁹⁷ This drug can also be offered as postexposure chemoprophylaxis to high-risk, highly susceptible individuals 3 months or older or to control institutional outbreaks. Its inhalational counterpart zanamivir is also effective against A and B strains of influenza and is approved to treat active disease in children 7 years or younger as well as for chemoprophylaxis in children 5 years and younger. To date, viral resistance to either drug remains low.⁹⁷

Unlike RSV, influenza is commonly associated with secondary bacterial pneumonia that is typically caused by *Streptococcus pneumoniae* or *Staphylococcus aureus*, making it especially important to consider appropriate empiric antimicrobial therapy when clinically appropriate.^{98,99}

Bacterial Pneumonia

In infants less than 3 days of age, group B streptococcus is the major causal pathogen of vertically transmitted “early-onset” neonatal pneumonia. Among infants up to about 3 months of age, *Listeria monocytogenes* and gram-negative enteric organisms join the list of principal causes of bacterial pneumonia and sepsis. The pathogenesis in this age group can involve local overgrowth and invasion of colonizing organisms through respiratory mucosa or hematogenous transmission of a blood-borne organism to the lower respiratory tract.^{85,100} Widespread maternal intrapartum antibiotic prophylaxis has influenced the incidence of perinatal GBS infection as well as its antimicrobial resistance patterns.¹⁰¹ The incidence of GBS sepsis has declined among very low-birth-weight infants in the era of ampicillin prophylaxis, while the incidence of *E. coli* sepsis (largely resistant to ampicillin) has increased in the same time period.¹⁰¹ Perinatally acquired *Chlamydia trachomatis* is another important cause of lower respiratory tract infection in infants up to 12 weeks of age.¹⁰⁰ Although uncommon, periodic epidemics of infection with *Bordetella pertussis* occur among incompletely immunized infants and children.¹⁰⁰ Apnea and intermittent cyanosis progressing to respiratory failure and shock can develop in young infants infected with *B. pertussis*, and clinicians should have a relatively low threshold for admitting these patients to the ICU.
